ABSTRACT

Context. X-shooter is the first second-generation instrument to become operative at the ESO Very Large Telescope (VLT). It is a broad-band medium-resolution spectrograph designed with gamma-ray burst (GRB) afterglow spectroscopy as one of its main science drivers.

Aims. During the first commissioning night on sky with the instrument fully assembled, X-shooter observed the afterglow of GRB 090313 as a demonstration of the instrument’s capabilities.

Methods. GRB 090313 was observed almost two days after the burst onset, when the object had already faded to $R \sim 21.6$. Furthermore, the 90% illuminated Moon was just 30 degrees away from the field. In spite of the adverse conditions, we obtained a spectrum that, for the first time in GRB research, simultaneously covers the range from 5700 to 23 000 Å. We mined the data for absorption signatures in the afterglow spectrum and to search for intervening systems at redshifts above $z = 1.5$.

Results. The spectrum shows multiple absorption features at a redshift of 3.3736, which we identify as the redshift of the GRB. These features are composed of 3 components with different ionisation levels and velocities. Some of the features have never been observed before in a GRB at such a high redshift. Furthermore, we detect two intervening systems at redshifts of 1.8005 and 1.9597.

Conclusions. These results demonstrate the potential of X-shooter in the GRB field, because it was capable of observing a GRB down to a magnitude limit that would include 72% of long GRB afterglows 2 h after the burst onset. Coupled with the rapid response mode available at VLT, allowing reaction times of just a few minutes, X-shooter constitutes a significant leap forward on medium resolution spectroscopic studies of GRBs, their host galaxies and intervening systems, probing the early history of the Universe.

Key words. gamma-ray burst: general – instrumentation: spectrographs

1. Introduction

During the first hours after the onset of long gamma-ray bursts (GRBs, for a short-long classification see Kouveliotou et al. 1993), their optical/near infrared (nIR) counterparts shine as the brightest beacons in the Universe (Kann et al. 2007; Racusin et al. 2008; Bloom et al. 2009). Because they are generally produced by the collapse of a massive star (Woosley & Bloom 2006, and references therein), they give us the opportunity to study the environment of massive star-forming regions at cosmological distances (the average redshift of long GRBs observed by Swift is $\sim 2.2$; Fynbo et al. 2009) through the use of medium-to-high resolution spectroscopy. Time variability of absorption features corresponding to fine-structure and metastable level transitions has sometimes been identified (Dessauges-Zavadsky et al. 2006; Vreeswijk et al. 2007; D’Elia et al. 2009), which makes it possible to constrain the distance from the GRB to the absorbing gas, on typical scales of kpc. Only a few such cases have been spotted up to now, because of the required spectral resolution and sensitivity. Furthermore, as bright sources that disappear over time, they allow us to study intervening systems through their absorption signatures in the afterglow spectrum and to search

* Based on observations made with ESO VLT at Paranal Observatory during the commissioning of X-shooter.
for the associated galaxies when the afterglow has faded away (Jakobsson et al. 2004; Chen et al. 2009).

The family of short GRBs, although still poorly studied, presents fainter counterparts on average and it has been suggested that it is produced by the coalescence of compact objects (Nakar 2007, and references therein), although some of them could come from other progenitors, such as extragalactic magnetars (Hurley et al. 2005). Up to now, there have been very few attempts to acquire a spectrum of a short GRB, most of them were unsuccessful because of late observations or faint afterglows. There is still no medium or high-resolution spectrum of a short GRB.

Within this context, X-shooter (D’Odorico et al. 2006) is presented to the GRB community. It is the first of the second-generation instruments at ESO’s Very Large Telescope (VLT) at Paranal Observatory (Chile). It is a single-target spectrograph capable of obtaining a medium-resolution spectrum ($R = 4000–14,000$, mainly depending on the slit width and wavelength) covering the complete range from 3000 to 24,800 Å in a single exposure. It has been designed to maximise efficiency by splitting the light with dichroics into three arms: ultraviolet/blue (UVB), visible (VIS), and near-infrared (NIR). Each arm has an echelle spectrograph with optimised optics, coatings, dispersive elements, and detectors. In March 2009, it was installed in the Cassegrain focus of Kueyen, the second 8.2 m Unit Telescope of the VLT, where it began routine scientific observations in October 2009.

One of the key science drivers of X-shooter is the study of optical and NIR afterglows of GRBs as cosmological probes of the circumstellar, interstellar, and intergalactic medium back to the epoch of first star formation in the Universe. During its first commissioning night on sky with its full setup, X-shooter was used to observe the afterglow of GRB 090313, which had exploded two days before, as a test target. In this article we present the results of this observation of a GRB with X-shooter, giving a hint of the full potential that the instrument will have during regular observations.

The paper is organised as follows. Section 2 describes our observations in the context of the GRB evolution. In Sect. 3 we present our results, focusing on the spectral features local to the GRB and on the intervening systems. Finally, in Sect. 4 we discuss the results and present our conclusions.

2. Observations

At 09:06:27 UT on 2009 March 13, Swift’s Burst Alert Telescope (BAT) detected GRB 090313 (Mao et al. 2009), a long-duration burst with $T_{90} = 78 \pm 19$ s (Sakamoto et al. 2009). In response to the trigger, the 0.76m Katzman Automatic Imaging Telescope (KAIT) slewed to the position shortly afterward and detected a bright ($R \sim 16$ mag) optical afterglow (Chornock et al. 2009a) at equatorial coordinates (J2000.0): RA = 13°13′36″21, Dec = +08°05′49″2 (Updike et al. 2009).

The afterglow evolved through a plateau phase (Perley et al. 2009b; de Ugarte Postigo et al. 2009b), during which it maintained a magnitude of $I \sim 17.7$ up to almost a day after the burst, when the light curve steepened (de Ugarte Postigo et al. 2009c) and decayed following a power law $F \propto t^{-1.73}$ (Perley et al. 2009a). Perley (2009) used multicolour photometry to study the spectral energy distribution of the afterglow, concluding that its intrinsic extinction followed a Small Magellanic Cloud profile with a V-band extinction $A_V \lesssim 0.4$. This value was later refined by Kann et al. (2009) to $A_V = 0.34 \pm 0.15$. They note that in the time interval between 0.02 and 0.5 days the afterglow

\caption{$I$-band acquisition image. The GRB afterglow is indicated with an arrow. We also marked the two galaxies identified by Berger (2009), as mentioned in the discussion, G1 and G2 (G2 is faintly visible ~2" NW of the afterglow). The figure shows the complete field of view of the acquisition and guiding camera, 90° × 90°. North and east are indicated in the figure.}
\end{figure}

The data were reduced using a standard procedure with a preliminary version of X-shooter’s pipeline (Goldoni et al. 2006, 2008). Because of variable conditions during the night of the observation, the spectra were not flux-calibrated, and a normalised spectrum is used in this work. No telluric correction was applied, so that prominent atmospheric bands (especially in the NIR) can

\footnotesize
\begin{itemize}
\item[1] http://www.sdss.org/DR7/algorithms/sdssUBVRITransform.html
\end{itemize}
still be seen in Fig. 2, where we show the reduced normalised spectrum, which is a combination of all the individual spectra, covering the useful observing range (where the afterglow was detectable above the background level). The wavelengths reported throughout the paper are in vacuum. The uncertainty in the wavelength calibration is of the order of 30 km s\(^{-1}\) when using the current pipeline, which is the dominant uncertainty when calculating the redshift. For the analysis of the spectral features, we used FITLYMAN (Fontana & Ballester 1995).

We caution that, because it was the first night of commissioning on sky, the instrument had not yet been optimised. Thus, the results presented here must not be considered as representing the optimal performance of the instrument but as a preliminary view of the potential that will be delivered by the instrument in regular operation. The results presented here supersede those reported by de Ugarte Postigo et al. (2009a).

3. Results

Over the complete range of the spectrum, we identify a main absorption system that is composed of several velocity components. To determine the central redshift of the absorption system, the spectra were rebinned such that the resulting absorption line centre represents the wavelength where the strongest absorption takes place. By excluding the blended absorption lines \(\text{C}\text{II}1334\) and \(\text{C}\text{II}\*1335.6, 1335.7\) from our calculations (see Sect. 3.1), we derive a redshift of 3.3736 ± 0.0004, which we identify as the redshift of the GRB. This value is consistent with the one previously determined by Chornock et al. (2009b) using GMOS/Gemini-South and Thöne et al. (2009) with FORS2/VLT.

Furthermore, we identify two intervening systems in the spectrum, one of which can again be divided into several velocity components. We determine the redshift in the same way as for the host galaxy system and derive redshifts of 3.1. The host galaxy system

3.1. The host galaxy system

Most of the absorption features detected at the redshift of the GRB can be separated into three different components that we name I, II, and III, where I has the highest redshift. We fix line profiles to the different components in order to determine the column density of each species. Because of the limited resolution and S/N, we fix the thermal \(b\)-parameter to 5 km s\(^{-1}\) and the turbulent \(b\)-parameters to 20 km s\(^{-1}\) (values that give the best global result for the fits), leaving only the column density as a free parameter. Transitions of the same element and ionisation level were fitted with a common column density. Some transitions are not well-fitted with only three components, which might indicate that there are other, smaller components not resolved in our spectrum. Furthermore, some of the lines are clearly saturated, so that only lower limits of the column densities can be derived for them. The results of the fits are displayed in Table 2. Transitions marked with brackets in the table are contaminated by skylines or blended, and have not been used to fit the column densities. Upper limits are 3\(\sigma\) or blended, and have not been used to fit the column densities.

Upper limits are 3\(\sigma\) or blended, and have not been used to fit the column densities. For saturated features we give lower limits for the column density. The fits to the highest S/N or least saturated transitions for each ion are shown in Fig. 3.

The exact number of components for Mg\(\text{II}\) is not known because of the contamination with skylines so we fitted just the outer components I and III. Moreover, saturation meant that we could derive only lower limits for the column densities of these components. For Mn\(\text{II}\), we could not fit component I owing to saturation, so we fitted just the outer components I and III. Moreover, the contamination with skylines so we fitted just the outer components I and III. Moreover, saturation meant that we could derive only lower limits for the column densities of these components. For Mn\(\text{II}\), we could not fit component I owing to contamination by skylines. The absorption bluewards of component III in Si\(\text{II}1526\) is produced by Fe\(\text{II}12382\) from the intervening system at redshift 1.80. We did not fit the O\(\text{I}1302\) transition because of the low S/N at the blue end of the spectrum. For weaker lines where we did not detect all three components, we give 3\(\sigma\) upper limits for those components unless those regions are affected by skylines or other absorption transitions.
The central component II is the one with the highest column density and, except for Fe ii, it could be fixed to 0 km s$^{-1}$. The blueshifted component III is around −85 km s$^{-1}$ for all elements where this component is present except for Fe ii where it lies at −47 km s$^{-1}$. For component I, the situation is slightly more complex. Al ii, Al iii, and Fe ii have component I at +102 km s$^{-1}$, whereas it is at +130 km s$^{-1}$ for the Si lines, as well as for Mg ii. Components I and III are absent for the weak lines Ca ii, Cr ii, and Zn ii. For Mg i we only detect components I and II, whereas for C iv we only detect components II and III. Fe ii has 3 components but at slightly different velocities than the other lines. We cannot confirm this behaviour securely by fitting other Fe ii lines, since the $\lambda$ 1608 Å line is the only one not severely affected by skylines. This behaviour of the different components might indicate that the absorbing material is not at the same place along the line-of-sight for different elements, which is expected if the absorption lines trace gas at different locations inside the host galaxy. Generally, we find that in component I the low ionisation species predominate over the higher ionisation species, while for component III the opposite is true. This is also confirmed by the ratio of column densities of Al iii and Al ii for which we get values of 0.03 ± 0.03, 0.14 ± 0.13, and 4.2 ± 0.9 for components I, II, and III, respectively. A similar behaviour is observed for the ratio of column densities of Si iv and Si ii with values of 0.02 ± 0.01, 0.91 ± 0.26, and 1.18 ± 0.14 for components I to III.

We detect the fine structure transitions of C ii $\lambda\lambda$ 1334, C ii $^\ast$ $\lambda\lambda$ 1335.6, 1335.7. The last two only have a 0.1 Å difference in central wavelength, so cannot be separated with the spectral resolution provided by X-shooter. However, the 1335.7 Å transition is 10 times stronger than the 1335.6 Å one, leading us to fit the absorption systems assuming that the stronger transition is responsible for most of the absorption. The resonant and fine-structure transitions are separated well enough to allow a fit of all 3 components for both lines. Only component III of the fine structure transition is rather close to component I of the resonant line, making the system blended. On the other hand, we cannot identify any Si ii $^\ast$ lines at the redshift of the GRB, which were...
reported for this GRB by Chornock et al. (2009b). However, our spectrum only covers the 1533.4 Å and the 1309.2 Å features and not at that 1264.7 Å, which is significantly stronger. We determined a 3-σ upper limit for Si II λ1533.4 of EW_{rest} < 0.21 Å and a limit for Si II λ1309.2 of EW_{rest} < 0.58 Å, the first being more constraining due to both the higher oscillator strength and S/N.

Combining the column density of all three components, we find a value of [Si/Fe] > 0.65 for the GRB host galaxy (reference solar composition obtained from Asplund et al. 2005). This high value of [Si/Fe] agrees with the work of Prochaska et al. (2007) for GRBs, who obtains higher values than those found for intervening absorbers in quasar spectra.

### 3.2. Intervening systems

An intervening system is identified at a redshift of 1.9597 through the detection of Fe II and Mg II in absorption (see Fig. 4 and Table 3).

At a redshift of 1.8005 we detect a further intervening system through several absorption features produced by low ionisation transitions (Fe II and Mg II), as well as neutral Mg I. This system is formed by three components with relative velocities of ~286 km s^{-1}, 0 km s^{-1}, and +85 km s^{-1} (see Fig. 5 and Table 4).

The absorber at z = 1.8 can be classified as a strong absorber (Mg II λ2796 EW_{rest} > 1 Å, see Table 1). Prochter et al. (2006) points out an excess (by a factor of ~4) in the frequency of strong Mg IIλ2796 absorbers in the line of sight of GRBs as compared to quasars. Recently, Vergani et al. (2009), have used a sample of GRB afterglow spectra that doubles the redshift path of previous studies to confirm this excess but only by a factor of ~2. The comparison is done using the SDSS QSO survey with a redshift range 0.37 < z < 2.27 and a 6-σ detection limit of the Mg IIλ2796 line. Following these criteria, the redshift path of the X-shooter spectrum of GRB 090313 for strong systems is Δz = 1.13, giving a number density of 0.88. This number density agrees with that of 0.70 ± 0.15 found by Vergani et al. (2009), whereas the number density of the strong Mg II systems found along QSO lines of sight is only 0.28 ± 0.01 (Nestor et al. 2005).

### 4. Discussion and conclusions

In this paper we present the first spectrum of a GRB obtained with X-shooter, covering a range from optical to NIR simultaneously for the first time. Although observed during an early commissioning phase and under unfavourable conditions, the results allow us to have an optimistic view of X-shooter’s potential.

For the GRB, we determined a redshift of 3.3736, at which we detect absorption features with three velocity components.
From the values in Table 2 and from Fig. 3 it is inferred that component II has the highest column densities, so we used it to calculate the redshift. Component I is the least ionised (high ionisation lines are only weakly detected), while in component III we mainly detect highly ionised species. Although not conclusive, this could indicate that component III is the closest to the GRB, while component I is the furthest. The relative velocities between the 3 different components come from the relative motion of the gas within the host galaxy, in principle unrelated to the GRB itself. The high values of [Si/Fe] measured in the GRB host galaxy may be indicative of enhanced abundance of Si (produced by extensive star formation) or a higher depletion level of Fe (evidence of dust). In fact, Kann et al. (2009) measure an extinction corresponding to $A_V = 0.34 \pm 0.15$ for this burst, which as they note, is atypically high for such a high redshift event. They also note that GRB 090313 is among the most intrinsically luminous optical afterglows detected. However, if we look at the $EW_{\text{rest}}$ measured for the absorption features in this spectrum (see Table 1), we find that they are consistent with the typical values found in the sample of Fynbo et al. (2009). We note that, to our knowledge, some features such as Mg II, Mg I and Ca II had not been observed before in GRB spectra at such high redshift.

The surveys of strong Mg II ($EW_{\text{rest}} > 1$ Å) intervening absorbers along GRB lines of sight gave the surprising result of an excess of these systems compared to QSO lines of sight (Prochter et al. 2006; Vergani et al. 2009). We measured the $EW_{\text{rest}}$ of the Mg II λ2796 line of both intervening systems, finding a combined value (coadd of the three components) of $1.35 \pm 0.10$ Å for the $z = 1.80$ and $0.50 \pm 0.03$ Å for the $z = 1.96$. 

---

**Fig. 3.** Fit of the detected transitions at the GRB redshift. For the elements with several lines detected, we show the transitions that are least saturated or have the highest S/N. The regions of the spectrum that are excluded from the fit because of the contamination by sky lines or other unrelated absorption features are drawn with a dashed line. We indicate the error spectrum with a dotted (blue) line. Vertical dotted (black) lines mark the different velocity components. See the electronic edition for a colour version of this figure.

**Fig. 4.** Fit of Mg II and Fe II lines of the intervening system at $z = 1.9597$.

**Fig. 5.** Fit of Mg I, Mg II, and Fe II lines of the intervening system at $z = 1.8005$, with three velocity components.
The number density of strong Mg\textsc{ii} systems for this spectrum is \(d\eta/dz = 0.88\), in agreement with the excess of a factor of \(\sim 2\) compared to the QSO lines of sight found by Vergani et al. (2009). The same authors also considered the statistics of weak systems (\(0.3 \AA < \Delta \lambda_{\text{rest}} < 1 \AA\)) and conclude that their number density agrees with what is found along QSO lines of sight, as confirmed by Tejos et al. (2009). The S/N of the GRB 090313 X-shooter spectrum is too low to cover a significant redshift path for a rest frame equivalent width limit of 0.3 \(\AA\); on the other hand, this limit will be normally reached for the guaranteed time programme for observations of GRB afterglows that will be performed with X-shooter. This programme will collect about 100 spectra within 3 years, hugely increasing the redshift path of the GRB surveys, hence the significance of the statistics, and bringing useful information to explain the unexpected excess of strong absorbers. Moreover, X-shooter will simultaneously cover a longer redshift path compared to the instruments presently used for QSO and GRB afterglow spectroscopic observations, up to \(z \Delta \sim 5\) (the total redshift path for strong Mg\textsc{ii} systems for the spectrum presented here is \(z \Delta = 2.1\)). Therefore X-shooter QSO and GRB surveys will be able to systematically investigate the presence and nature of Mg\textsc{ii} systems up to a much higher redshift than currently done.

No significant emission lines have been detected at the redshifts of the GRB or in any of the intervening systems. Berger (2009) points out the presence of two galaxies near the afterglow (G1 and G2, see Fig. 1). The brightest one (G1, \(r' = 15.6\)) has a known redshift of \(z = 0.0235\) and is located at 17'8 from the afterglow, equivalent to 8.3 kpc projected at the redshift of the galaxy. We do not see any features at this redshift and, in particular, nothing is detected at the wavelength of the most prominent absorption features that can be seen in the SDSS spectrum of G1 (Abazajian et al. 2009), which are the Ca\textsc{ii} lines at 3968, 3933, 8544, 8664, and Na\textsc{i} lines at 5891, 5897. The Ca\textsc{ii} features are not detected with 3-\(\sigma\) limits of \(EW_{\text{rest}} < 0.6 \AA\) and Na\textsc{i} with limits of \(EW_{\text{rest}} < 1.2 \AA\). The closest galaxy, G2 at 2',3 with \(r' = 21.6\) does not have an identified redshift, so its relation with any of the observed absorption features will need further investigation.

To conclude, we point out some facts that show X-shooter's potential in the GRB field. Given a 10-\(\sigma\) limiting magnitude (per spectral bin) of \(R \sim 21.0\) with 1 h exposure, it will be able to study 33\% (72\%) of the long bursts 12 (2) h after the onset (using optical fluxes and decay indices from Nysewander et al. 2009). The same authors also considered the statistics of weak absorbers. Moreover, X-shooter will simultaneously cover a longer redshift path compared to the instruments presently used for QSO and GRB afterglow spectroscopic observations, up to \(z \Delta \sim 5\) (the total redshift path for strong Mg\textsc{ii} systems for the spectrum presented here is \(z \Delta = 2.1\)). Therefore X-shooter QSO and GRB surveys will be able to systematically investigate the presence and nature of Mg\textsc{ii} systems up to a much higher redshift than currently done.

No significant emission lines have been detected at the redshifts of the GRB or in any of the intervening systems. Berger (2009) points out the presence of two galaxies near the afterglow (G1 and G2, see Fig. 1). The brightest one (G1, \(r' = 15.6\)) has a known redshift of \(z = 0.0235\) and is located at 17'8 from the afterglow, equivalent to 8.3 kpc projected at the redshift of the galaxy. We do not see any features at this redshift and, in particular, nothing is detected at the wavelength of the most prominent absorption features that can be seen in the SDSS spectrum of G1 (Abazajian et al. 2009), which are the Ca\textsc{ii} lines at 3968, 3933, 8544, 8664, and Na\textsc{i} lines at 5891, 5897. The Ca\textsc{ii} features are not detected with 3-\(\sigma\) limits of \(EW_{\text{rest}} < 0.6 \AA\) and Na\textsc{i} with limits of \(EW_{\text{rest}} < 1.2 \AA\). The closest galaxy, G2 at 2',3 with \(r' = 21.6\) does not have an identified redshift, so its relation with any of the observed absorption features will need further investigation.

To conclude, we point out some facts that show X-shooter’s potential in the GRB field. Given a 10-\(\sigma\) limiting magnitude (per spectral bin) of \(R \sim 21.0\) with 1 h exposure, it will be able to study 33\% (72\%) of the long bursts 12 (2) h after the onset (using optical fluxes and decay indices from Nysewander et al. 2009). As an example, X-shooter would have been able to obtain a spectrum similar to or better than the one presented here of the \(z \sim 8.2\) GRB 090423 (Tanvir et al. 2009; Salvaterra et al. 2009) during the first 24 h and to follow the nearby GRB 030329 for over a month. If we consider short GRBs, we expect to be able to study 3\% (17\%) within 12 (2) h of the burst onset. Together with the rapid response mode available at VLT, which allows reaction times of just a few minutes, the possibilities increase. With its intermediate resolution, we will distinguish components with differential velocities of \(\sim 30 \text{ km s}^{-1}\). As shown here, this resolution will allow abundances of the different element species to be derived through line fitting, although with some limitations as compared to higher resolution spectrographs when fitting blended components or marginally saturated lines. Thanks to the wide wavelength coverage, it will be capable of observing afterglows up to redshifts of \(\sim 18\), assuming that they exist (at redshift 18, Ly-\(\alpha\) would lie at \(\sim 23000 \AA\)). It will allow systematic studies of lines over wide redshift ranges (Mg \textsc{ii}, \(12796, 2803\) will be detectable from \(z = 0.1\) up to \(z = 7.5\)), as well as measurements of ratios with widely separated lines. Furthermore, through the wide spectral coverage, we will have more lines to determine metallicities with better accuracy. It will also allow study of dust extinction profiles in GRB environments. Thanks to the increased sensitivity compared to other instruments of similar resolution, we will be able to study feature variability with higher time resolution and up to later times. All these places X-shooter in a position to lead breakthrough advances in GRB research in the next years.
