(Received 9 March 2010; accepted 24 June 2010; published online 6 October 2010)

We report a joint experimental and theoretical study that directly tests the quality of the potential energy surfaces used to calculate energy changing cross sections of water in collision with helium and molecular hydrogen, at conditions relevant for astrophysics. Fully state-to-state differential cross sections are measured for H2O–He and H2O–H2 collisions at 429 and 575 cm−1 collision energy, respectively. We compare these differential cross sections with theoretical ones for H2O+H2 derived from state-of-the-art potential energy surfaces [P. Valiron et al., J. Chem. Phys. 129, 134306 (2008)] and quantum scattering calculations. This detailed comparison forms a stringent test of the validity of astrophysics calculations for energy changing rates in water. The agreement between theory and experiment is striking for most of the state-to-state differential cross sections measured. © 2010 American Institute of Physics. [doi:10.1063/1.3475517]

Interpretation of the molecular rotational spectra delivered by Earth and space-borne telescopes is a complex process requiring knowledge of molecular state-to-state collisional excitation rates over a broad range of temperatures and transitions. Because these rates for energy changing (inelastic) collisions are not usually known experimentally,1,2 astronomical models rely predominantly on theoretical estimates that require accurate intermolecular potential energy surfaces (PESs). Water is the most abundant polyatomic molecule in the Galaxy. Detailed knowledge of the energy transfer rates and mechanisms for water is critical in many astrophysical applications, including line transfer, thermal balance of interstellar clouds, and the occurrence of astrophysical masers.3

Our work is designed to test the PES describing the interaction of H2O with H2 and He, which are the dominant colliders in most astronomical environments. A stringent test of the accuracy of a PES is its ability to predict state-to-state differential cross sections (DCSs), which are sensitive probes of those regions of the interaction potential that govern energy transfer. In media with little ionization, water molecules collide with H2 molecules in one of the lowest rotational states, or with He atoms, at collision energies in the range from a few cm−1 to a few hundreds of cm−1.4,5 In our laboratory, we collide H2O with >90% in its lowest rotational state with H2 or He at collision energies of 575 and 429 cm−1, respectively.

Previous experiments by Buck and co-workers5 measured partially state-resolved DCSs for He+H2O scattering. Nesbitt and co-workers6 reported state-selective integral cross section measurements for H2O+argon scattering. Cappelletti and co-workers7,8 measured total integral cross sections for H2O+ rare gas scattering. Our specific goal here is to determine the angular distribution in the center of mass frame of the nascent excited H2O state flux created by scattering the ground state H2O by H2 or He. Such a measurement is now possible using the velocity mapping imaging (VMI) method9,10.

The experimental procedure and VMI apparatus is described in Ref. 11 and is similar to that of Ref. 10. Full details of the apparatus11 and the nascent water laser ionization detection method12 will be given in forthcoming publications. In short, molecular beams of water and H2 or He are crossed at 90°, where H2O and H2 are prepared predominately in their lowest possible rotational states. Collisions produce nascent H2O in higher rotational states. State selective ionization under velocity mapping conditions produces an image of the nascent final state three-dimensional velocity distribution. A typical raw image is shown in Fig. 2(a). Experimental conditions are optimized to minimize the formation of water clusters. Our experiment detects water monomers; if water clusters arise from scattering water, the location and size of the Newton sphere (Fig. 2) will be quite different from that of a monomer collision because of the different kinematics and the dynamics of the cluster dissociation. The images shown in Fig. 2 display no evidence of cluster contributions. We assume that clusters do not affect the results of this study.

In Fig. 2, the rotational quantum states of H2O are labeled J K_a K_c, where J is the total rotational angular momentum, and K_a and K_c are projections of J on the a and c rotation axis. The nuclear spin statistics of two identical hydrogen atoms results in two forms of H2O, ortho (K_a+K_c =odd), and para (K_a+K_c =even), and two forms of H2, para (J=even) and ortho (J=odd). Inelastic collisions conserve...

FIG. 1. Schematic of the crossed-beam VMI apparatus. Pulsed molecular
beam expansions of pure H2 or He and H2O in Ar are skimmed and crossed
at 90°. Newly formed rotationally excited H2O is state selectively ionized by
a pulsed laser operating around 248 nm. The H2O+ ions are projected by a
VMI lens to a two-dimensional imaging detector monitored by a charge
coupled device (CCD) camera. Normal H2 was converted to para-H2 using
an iron oxide catalyst at 20 K and was then expanded through a pulsed valve
externally cooled by cold N2 gas to a temperature of 170 K in order to
decrease the population of H2(J=2).

ortho-para symmetry.6
Images collected with the H2O and H2 or He beam separ-
ated in time were subtracted from images collected in opti-
mal time overlap for background correction. A set of
background-corrected images is shown in Fig. 2(b). These
images are density maps of nascent H2O; conversion to the
desired flux map is carried out using the IMSIM software
procedure,13,14 which reproduces a simulated density image
in quantitative agreement with the raw images. The derived
flux angular distributions (DCSs, \(d\sigma/d\Omega\)) for the selected
images are shown as black lines in the panels of Fig. 3.

An important experimental observation is that for the
same final states at nearly the same collision energy, water
scatters much more strongly in the forward direction (defined
in Fig. 2) due to collisions with H2 compared to He. Chang-
ing the H2 supersonic beam conditions (using para-H2 versus
normal-H2 and cooling the H2 nozzle assembly from \(\sim 330\)
to 170 K), we find that the scattering remains strongly in
the forward direction. Forward scattering is thus favored for all
rotational states of H2. Hence, an important difference be-
tween H2 and He is indicated in our differential measure-
ments, even when scattering is for the most part by
para-H2(J=0), which is often assumed to behave similarly to
He.15

The experimental data are compared here with DCS pre-
dictions from a fully quantum analysis using the most recent
and advanced PES for the nonreactive systems H2O+He (Ref. 16)
and H2O+H2.17,18 Few such calculations exist in literature.1,19 For the H2O+H2 case, a full nine-dimensional PES
(including all inter- and intramolecular degrees of freedom)
was obtained from Ref. 18. This nine-dimensional PES
was averaged over the vibrational ground state wave func-
tions of H2O and H2, yielding a five-dimensional rigid-body
PES. This latter PES has been used to calculate many energy
changing cross sections and rates relevant for astrophysics,20–22 making it all the more important to per-
form the present evaluation. The H2O–He PES was derived
from the PES of Hodges et al.16 using their routines as input
in our fitting scheme, which is similar to the original scheme
of Green et al.23

The scattering S-matrices needed for computing DCSs for both H2O–H2 and H2O–He were calculated by employ-
ing the close coupling formalism implemented in the
MOLSCAT program.24 For H2 with \(J=1,2\), the DCS calcu-
lation made use of an algorithm derived from the original DCS
formulas.25 Inelastic cross sections of interest were con-
verged to 1%. For the specific angles 90°, 135°, and 180° in the DCS plotted in Fig. 3. The lower left diagonal arrow shows the
propagation direction of the ionization laser beam. (b) Background sub-
tracted images of inelastically scattered H2O in the indicated final \(J_{c},K_{c}\)
state for collisions with para-H2 and He.

...experimental collision energy ...E \(\text{collision}\) to 1%. For the specific angles 90°, 135°, and 180°, the convergence of DCSs was checked again for a conve-
...greater than 0.5%. The experimental collision energy spread is about \(\pm 10\%\), so we checked the sensitivity of the computed DCS to \(E \text{collision}\). The sensitivity was marginal, which is expected since the experiments sample transitions between the lowest rotational levels of H2O, and all scattering resonances for those transitions occur at much lower \(E \text{collision}\).26,27 In the case of He, very similar DCS results were obtained in Ref. 5, providing an independent check of our method.

To compare the computed DCS with the experiment for

FIG. 2. (a) Raw image of H2O in the \((J_{c},K_{c})=1_{1}\) final state created by
scattering of H2O(1_{1}) with helium. A color bar on the left side shows the
linear intensity scale for the signal. Three signals are seen; a trace amount of
water in the He beam \((v_{\text{He}}, \text{vertical direction})\), the residual (\(-5\%\)) popula-
tion of H2O(1_{0}) in the water beam \((v_{\text{H2O}}, \text{horizontal direction})\), and the
two-dimensional projection of the three-dimensional Newton sphere moving
at the center of mass velocity \((v_{\text{CM}})\). The dashed circle indicates the size of
the Newton sphere for elastic scattering and the directions described as
forward, side, and backscattering in the center-of-mass frame (0°, 90°, and
180° in the DCS plotted in Fig. 3). The lower left diagonal arrow shows the
propagation direction of the ionization laser beam. (b) Background sub-
tracted images of inelastically scattered H2O in the indicated final \(J_{c},K_{c}\)
state for collisions with para-H2 and He.

...experimental collision energy spread is about \(\pm 10\%\), so we checked the sensitivity of the computed DCS to \(E \text{collision}\). The sensitivity was marginal, which is expected since the experiments sample transitions between the lowest rotational levels of H2O, and all scattering resonances for those transitions occur at much lower \(E \text{collision}\).26,27 In the case of He, very similar DCS results were obtained in Ref. 5, providing an independent check of our method.

To compare the computed DCS with the experiment for
the H$_2$O-para-H$_2$ collision (rotational temperature of para-H$_2 \approx 220$ K), we averaged the theoretical DCSs over a rotational distribution in the H$_2$ beam of 61% H$_2$(J=0), 10% H$_2$(J=1), and 29% H$_2$(J=2), as measured experimentally using (2+1) Resonance Enhanced Multi-Photon Ionization (REMPI) of H$_2$ around 200 nm. Collisions resulting in H$_2$(J) changing cross sections were both measured [using 2+1 REMPI of H$_2$(J=1,2) at ~200 nm] and calculated to be negligible. Comparisons of the experimental and fully quantum calculated DCSs plotted in Fig. 3 show remarkably good agreement for both the H$_2$O+He and the H$_2$O+para-H$_2$ systems. We have not smoothed any possible quantum oscillations appearing in the theoretical DCS. Some remnants of the oscillations averaged over the experimental resolution may be visible at the experimental level.

For the sake of comparisons between He and para-H$_2$ scattering, we also show computed DCSs for scattering between water and para-H$_2$ using the H$_2$ J=0,2 rotor states in the channel basis as before, but considering only J=0 initial and final states. In this calculation, the coupled channel propagation used for computation of the S matrix elements includes a full description of molecular H$_2$, including its anisotropy, but the partial wave sum used for construction of the DCS from the S matrix elements is identical to that for H$_2$O–H$_2$ collisions. The results are shown as blue lines in the left panels of Fig. 3. In this case, the DCS structure becomes very different from the results that include an average over the experimental rotational state distribution. The strong forward scattering disappears and the overall structure becomes qualitatively similar to scattering of H$_2$O by He. Very similar results were obtained when only J=0 was included in the H$_2$ rotor basis, that is, when H$_2$ was treated as an atom in the scattering calculation. Apparently the most important difference between scattering by He and by H$_2$ (J=0) is the different shape of the potential; in particular, the well is deeper for H$_2$. While no attempt is given here to compare absolute values of cross sections, the computed DCSs for He and for H$_2$(J=0–0) show strong similarities at the energies studied, away from the resonance regimes.

H$_2$O–H$_2$ scattering is thus quite sensitive to the initial rotational state of the H$_2$, even though most collisions result in no change in its rotational state. Ignoring this dependence and treating all H$_2$ molecules as J=0 molecules or as atoms can introduce important errors. The common procedure of estimating rates for para-H$_2$ collisions with those from simpler He calculations should thus be applied with caution.

Differences in the scattering of water by para-H$_2$ and normal-H$_2$ have been found in pressure broadening experiments and simulations at 50< T <200 K. The present experiments, however, did not detect a qualitative change in the DCS changes in H$_2$ beam conditions. In our experiment, it is not possible to produce a beam of pure para-H$_2$(J=0). Even at the nozzle temperature of 170 K, the expected population ratio of para-H$_2$(J=0) to para-H$_2$(J=2) is still 4.3:1. Replacing normal-H$_2$ by para-H$_2$ at this temperature in our apparatus produced beams with measured H$_2$ populations in J>0 states of 28%, and the observed images had quite similar angular distributions to those observed under other beam conditions. It is likely that this state distribution was not pure enough to reveal the He-like DCS predicted by the calculation.

In summary, experiments are now possible that provide sensitive information in the form of state-to-state differential cross sections for collisions of H$_2$O with H$_2$, He, and other species under conditions relevant to those of interstellar space. Although the center-of-mass energy tested here is somewhat higher than the usual energies found in interstellar matter, the shape of the PES has been thoroughly tested, setting great confidence in the calculating scheme that we used to obtain the PES. The measured and calculated properties for the most part agree quite well, giving confidence in the quality of the PESs describing the H$_2$O–H$_2$ and H$_2$O–He interactions. The PESs for H$_2$O interaction with He and H$_2$ in general appear to pass the experimental DCS test with flying colors. Our results point out the differences between collisions of water with helium and with cold para-H$_2$, and suggest similarities in the shape of the DCS for all initial H$_2$(J) states.

Various tests at lower collision energies, including H$_2$–H$_2$O cluster spectroscopy, and scattering experiments testing the resonance or elastic regimes should be undertaken in parallel with more global tests such as pressure broadening or virial coefficient measurements. All these tests
comparing theory with experiment help assess the validity of the H$_2$O–H$_2$ PES of paramount importance to understanding of the abundance and role of water in the interstellar matter.
