(Dated: July 30, 2010)

We develop a first-principles theory of resonant impurities in graphene and show that a broad range of realistic impurities leads to the characteristic sublinear dependence of the conductivity on the carrier concentration. By means of density functional calculations various organic groups as well as ad-atoms like H absorbed to graphene are shown to create midgap states within ±0.03 eV around the neutrality point. A low energy tight-binding (TB) description is mapped out. Boltzmann transport theory as well as a numerically exact Kubo formula approach yield the conductivity of graphene contaminated with realistic impurities in accordance with recent experiments.

The mechanism determining the charge carrier mobility of present graphene samples is being controversially debated. The main experimental fact requiring an explanation is that, away from the neutrality point, the conductivity of graphene is weakly temperature dependent and approximately proportional to the carrier concentration n at 1, 2. This definitely requires the assumption of some long-range interactions with scattering centers. The Coulomb interaction with charge impurities is an “explanation by default” 3. However, it seems that some experimental data cannot be explained in this way, especially, a relatively weak sensitivity of the electron mobility to dielectric screening 4. Thus, alternative scattering mechanisms are also discussed, such as frozen ripples 5 and resonant scatterers 5–8. In the first case the long-range character of the interactions is due to the long-range character of elastic deformations and in the second one due to divergence of the scattering length. New experimental data 9 seem to support the latter possibility.

Theoretically, both suggestions face with serious problems. The “ripple” mechanism requires quenching of the thermal bending fluctuations 5, 10, but there are still no realistic scenarios of such a quenching. Resonant scattering naturally appears for vacancies 8 but they do not exist, in noticeable concentrations, in graphene samples if they are not created artificially, e.g., by irradiation 11. Adsorbates on graphene can provide resonances (quasiloc lized states) close enough to the neutrality point 12–15 but not necessarily 12, 16. For impurity resonances some 100 meV off the neutrality point the conductivity should display a pronounced electron-hole asymmetry 16 which is not observed in experiments. So, it is not clear whether resonant impurity scattering can be the main limiting factor in a general case.

In this Letter, we build a first-principles theory of electron scattering by realistic resonant impurities, such as various organic molecules which are always present in exfoliated graphene samples 17, 18. Combining the Boltzmann equation approach and a numerically exact Kubo formula consideration with first-principles parameters, we show that this class of impurities can limit electron transport in typical exfoliated graphene samples and explain the experimentally observed concentration dependence of the conductivity.

Exfoliated graphene samples are contaminated with long polymer chains 17, 18. Most important about these contaminants is their possibility to form a chemical bond to carbon atoms from the graphene sheet. To model such a situation we carry out density functional theory (DFT) calculations of graphene with adsorbed CH 3, C 2H 5, CH 2OH (as simplest examples of different organic groups), as well as H and OH groups. From the resulting supercell band structures we derive effective interaction parameters entering a TB model and find that the exact chemical composition is not essential: the parameters are very similar for all adsorbates except for the case of hydroxyl. This facilitates us to obtain the effect of the contamination on the electron conductivity.

An atomistic description of the graphene adsorbate systems is achieved by DFT calculations within the generalized gradient approximation (GGA) 19 on 3×3×9×9 graphene supercells containing one impurity. Using the Vienna Ab Initio Simulation Package (VASP) 20 with the projector augmented wave (PAW) 21, 22 basis sets, we obtain fully relaxed adsorption geometries and calculate the supercell band structures.

The DFT results for CH 3, C 2H 5, CH 2OH on graphene are shown in Fig. 1a and compared to H and OH adsorbates. All of these impurities bind covalently to graphene and create a midgap state as characteristic for monovalent impurities 15. For all adsorbates except OH the midgap state lies within ±0.03 eV around the neutrality point. As the supercell band structures for the organic groups and for H on graphene virtually coincide within an energy range of more than ±1 eV, it becomes clear that the parameters of the midgap state depend very weakly on the adsorbed group and, thus, can be considered as robust for further use in the transport theory.

For an analytical description of these systems we start
with a TB model of graphene,
\[ \hat{H} = -t \sum_{\langle i, j \rangle} c_i^\dagger c_j, \]  
where \( c_i \) denotes the Fermi operator of an electron in the carbon \( p_z \) orbital at site \( i \), the sum includes all pairs of nearest-neighbor carbon atoms, and \( t \approx 2.6 \) eV is the nearest-neighbor hopping parameter. In this framework, we consider a “non-interacting Anderson impurity”, adding to the (1) the localized state, \( \hat{H}_{\text{imp}} = \epsilon_d d^\dagger d \), with on-site energy \( \epsilon_d \) and corresponding Fermi operator \( d \), which is coupled to the graphene bands by \( \hat{V} = V c_i^\dagger d + \text{H.c.} \).

To describe electron transport in pristine as well as doped graphene correctly, the analytical model has to recover the realistic system within an energy window of some 100 meV around the neutrality point. Applying the same supercell boundary conditions as in the DFT simulations to the TB impurity model, we obtain the TB supercell band structures as depicted in Fig. 1 b. The band structure of graphene with a methyl group is well recovered as supercell band structures as depicted in Fig. 1 b. The scattering of electrons caused by resonant impurities is described by the T-matrix (for a review, see Ref. [14])

\[ T(E) = \frac{1}{E - \epsilon_d - V c_i^\dagger d + \text{H.c.}} \]

where \( \epsilon_d \) is the energy of the midgap state. The impurity model parameters obtained from DFT lead to resonances in an energy region of ±0.03 eV around the Dirac point, which proves consistency of our TB model with DFT.

In the Boltzmann equation approach, the T-matrix can be used to estimate the conductivity \( \sigma \)

\[ \sigma = \frac{2 e^2}{h} v_F k_F \tau \]

where \( v_F \) is the Fermi velocity and \( k_F \) is the Fermi wave vector. For a concentration of \( n_t \) impurities per carbon atom, the scattering rate reads as

\[ \tau^{-1} = \frac{2 \pi}{h} n_t |T(E_F)|^2 \]

yielding the conductivity

\[ \sigma \approx \frac{(2 e^2)}{h} \frac{2 n_t}{\pi n_c \ln \left( \frac{E_F}{D} \right)} \]

where \( n_c = E_F^2/D^2 \) is the number of charge carriers per carbon atom. Eq. (3) yields the same behavior as for vacancies [8]. In the case of the resonance shifted with respect to the neutrality point the consideration of Ref. [7] leads to the dependence

\[ \sigma \propto (q_0 \pm k_F \ln k_F R)^2 \]

where \( \pm \) corresponds to electron and hole doping, respectively, and \( R \) is the effective impurity radius.

We now investigate to which extend realistic resonant impurities create sublinear behavior similar to Eqs. (3-4). To this end, we first estimate the conductivity according to Eq. (2) for different types of impurities (Fig. 2). For the resonant scatterers from Fig. 1 (except for OH) the conductivity curves are expected to lie within the region bounded by the curves belonging to \( \epsilon_d = -0.26 \) eV and \( \epsilon_d = 0.26 \) eV. These curves are very similar to V-shape experimental curves [1, 2, 4, 9] and can be roughly fitted to the limit of Eqs. (3) and (4). The effective radius \( R \) resulting from Eq. (3) is \( D/h v_F \approx 0.9 \) Å and has been also used in the fit according to Eq. (4) in Fig. 2.
has been observed [9, 11] with effective impurity radii in the range of \( R = 2.3 - 2.9 \text{Å} \). However, any estimation of effective radii should be considered only qualitatively, as \( D \) and \( R \) enter the conductivity logarithmically and a wide range of cut-offs lead to similar conductivity curves.

The result for impurities with \( V = 2t \) and \( \epsilon_d = 1.7 \text{eV} \), which corresponds to H ad-atoms in the model of Ref. [16], differs qualitatively from our results and from experimental data which emphasizes the crucial importance of a careful first-principles determination of the model parameters. In our model and for the charge carrier concentration being varied within \( |n_e| < 0.003/\text{C-atom}=1.1 \cdot 10^{13} \text{cm}^{-2} \), impurities like CH₃, C₂H₅, CH₂OH, or H attached to graphene lead to a Boltzmann conductivity with one distinct minimum close to the neutrality point.

At low charge carrier concentrations or high impurity concentrations, the Boltzmann approach becomes questionable. To understand the on-set of this parameter regime and the behavior of the conductivity in this regime, we performed numerically exact calculations of the conductivity in the TB model (1) using the Kubo formula. [See [25].] The results for two types of resonant scatterers, adsorbed atoms with \( \epsilon_d = -t/16 \), \( V = 2t \) resembling CH₂ groups, and for vacancies are shown in Fig. 3. One can see that the Boltzmann equation is applicable only for impurity concentrations smaller than a few percent per site (already for 5% the difference in concentration dependence is essential). The Boltzmann approach does not work near the neutrality point where quantum corrections are dominant [6, 26, 27]. In the range of concentrations, where the Boltzmann approach is applicable the conductivity as a function of energy fits very well the dependence of Eq. (4), with \( q_0 = 0.02 \text{Å}^{-1} \), \( R = 0.6 \text{Å} \) for \( n_i = 0.1\% \), and \( q_0 = 0, R = 0.5 \text{Å} \) for \( n_x = 0.1\% \) with \( k_F = E_F/\hbar v_F \) as in clean graphene.

Close to the neutrality point the conductivity deviates from the Boltzmann equation result of Eq. (2). Boltzmann theory is not capable of yielding \( \sigma = 4e^2/\pi \hbar \) for clean graphene at the neutrality point [6, 26]. Moreover, resonant impurities lead to the formation of a low energy impurity band (see increased DOS at low energies in Fig. 4). At impurity concentrations on the order of a few percent (Fig. 3 c,d) this impurity band contributes to the conductivity and can lead to a maximum of \( \sigma \) in the midgap region. Moreover, the impurity band can host two electrons per impurity. For impurity concentrations below \( \sim 5\% \), this leads to a plateau shaped minimum of width \( 2n_i \) (or \( 2n_x \)) in the conductivity vs. \( n_e \) curves around the neutrality point. Analyzing the
plateau width in experimental data (similar to the analysis for $N_{2}O_{4}$ acceptor states in Ref. 13) can, thus, yield an independent estimate of impurity concentrations. For chiral disorder [28, 29] corresponding to the resonant impurities considered, here, as well as short range disorder [30, 31] (anti)localization effects can become important in cases like graphene, where impurity concentrations are varied between a few percent and 100%. In clean micron size samples with realistic impurity concentrations on the order of $n_{i} = 0.01\%-0.1\%$ these effects present merely corrections: Upon doubling the simulation cell length (4096 $\times$ 4096 $\rightarrow$ 8192 $\times$ 8192) at $n_{i} = 0.1\%$ the changes of the conductivity at the neutrality point are below 10%.

Electron scattering in bilayer graphene has been proven to differ essentially from the single layer case in Ref. 32: For a scattering potential with radius much smaller than the de Broglie wavelength of electrons, the phase shift of s-wave scattering $\delta_{0}$ tends to a constant as $k \rightarrow 0$. Therefore, within the limit of applicability of the Boltzmann equation, the conductivity of a bilayer should be just linear in $n_{e}$, instead of sublinear dependence (4) for the single layer. The difference is that in the single layer, due to vanishing DOS at the Dirac point, the scattering disappears at small wave vectors as $k_{R}$ on the order of $n_{e} = 10^{5}$ the changes of the conductivity at the neutrality point are below 10%.

In summary, we have demonstrated that realistic impurities in graphene frequently cause quasilocal peaks nearby the neutrality point. In particular, for various organic groups the formation of a carbon-carbon bond results in the appearance of midgap (resonant) states within $\pm 0.03$ eV around the neutrality point. They can be described as Anderson impurities with the hybridization parameter of about $2t$ and on-site energies on the order of $|e_{d}| \sim t/10$. The resonant scattering model with these parameters describes satisfactory experimental data on the concentration dependence of charge carrier mobility for graphene.

We thank L. Oroszläny and H. Schomerus for discussions of Ref. 16. Support from SFB 668 (Germany), the Cluster of Excellence "Nanospintronics" (LEXl Hamburg), FOM (The Netherlands) and computer time at HLRN (Germany) and NCF (The Netherlands) are acknowledged.

[34] The hybridization parameter $V$ should not be confused with the avoided crossing strength from Ref. 15. The latter is supercell specific, in contrast to $V$ used here.
