We present an updated measurement of the anomalous like-sign dimuon charge asymmetry $A^b_{sl}$ for semi-leptonic $b$-hadron decays in 9.0 fb$^{-1}$ of $p\bar{p}$ collisions recorded with the D0 detector at a center-of-mass energy of $\sqrt{s} = 1.96$ TeV at the Fermilab Tevatron collider. We obtain $A^b_{sl} = (-0.787 \pm 0.172 \text{ (stat)} \pm 0.093 \text{ (syst)})\%$. This result differs by 3.9 standard deviations from the prediction of the standard model and provides evidence for anomalously large $CP$ violation in semi-leptonic neutral $B$ decay. The dependence of the asymmetry on the muon impact parameter is consistent with the hypothesis that it originates from semi-leptonic $b$-hadron decays.

PACS numbers: 13.25.Hw; 14.40.Nd; 11.30.Er

I. INTRODUCTION

We measure the like-sign dimuon charge asymmetry of semi-leptonic decays of $b$ hadrons,

$$A^b_{sl} \equiv \frac{N^{++}_b - N^{-+}_b}{N^{++}_b + N^{-+}_b},$$

in 9.0 fb$^{-1}$ of $p\bar{p}$ collisions recorded with the D0 detector at a center-of-mass energy $\sqrt{s} = 1.96$ TeV at the Fermilab Tevatron collider. Here $N^{++}_b$ and $N^{-+}_b$ are the number of events containing two positively charged or two negatively charged muons, respectively, both of which are produced in prompt semi-leptonic $b$-hadron decays. At the Fermilab Tevatron $p\bar{p}$ collider, $b$ quarks are produced mainly in $b\bar{b}$ pairs. Hence, to observe an event with two like-sign muons from semi-leptonic $b$-hadron decay, one of the hadrons must be a $B^0$ or $B^0_s$ meson that oscillates and decays to a muon of charge opposite of that expected from the original $b$ quark [1]. The oscillation $B^0_q \leftrightarrow B^0_q$ ($q = d$ or $s$) is described by higher order loop diagrams that are sensitive to hypothetical particles that may not be directly accessible at the Tevatron.

The asymmetry $A^b_{sl}$ has contributions from the semi-leptonic charge asymmetries $a^d_{sl}$ and $a^s_{sl}$ of $B^0$ and $B^0_s$ mesons [2], respectively:

$$A^b_{sl} = C_d a^d_{sl} + C_s a^s_{sl},$$

with $a^d_{sl} = \frac{\Delta \Gamma_q}{\Delta M_q} \tan \phi_q,$

where $\phi_q$ is a $CP$-violating phase, and $\Delta M_q$ and $\Delta \Gamma_q$ are
the mass and width differences between the eigenstates of the propagation matrices of the neutral $B^0_s$ mesons. The coefficients $C_d$ and $C_s$ depend on the mean mixing probability, $\chi_0$, and the production rates of $B^0$ and $B^0_s$ mesons. We use the values of these quantities measured at LEP as averaged by the Heavy Flavor Averaging Group (HFAG) [3] and obtain

\[ C_d = 0.594 \pm 0.022, \]
\[ C_s = 0.406 \pm 0.022. \] (4)

The value of $\chi_0$ measured by the CDF Collaboration recently [4] is consistent with the LEP value, which supports this choice of parameters. Using the standard model (SM) prediction for $a^{(d)}_s$ and $a^{(s)}_s$ [5], we find

\[ A^b_{a1}(SM) = (-0.028^{+0.005}_{-0.006})\%, \] (5)

which is negligible compared to present experimental sensitivity. Additional contributions to CP violation via loop diagrams appear in some extensions of the SM and can result in an asymmetry $A^b_{a1}$ within experimental reach [6–10].

This Article is an update to Ref. [11] that reported evidence for an anomalous like-sign dimuon charge asymmetry with $6.1\text{ fb}^{-1}$ of data, at the 3.2 standard deviation level. All notations used here are given in Ref. [11]. This new measurement is based on a larger dataset and further improvements in the measurement technique. In addition, the asymmetry’s dependence on the muon impact parameter (IP) [12] is studied. The D0 detector is described in Ref. [13]. We include a brief overview of the analysis in Sec. II. Improvements made to muon selections are presented in Sec. III; the measurement of all quantities required to determine the asymmetry $A^b_{a1}$ is described in Secs. IV–X, and the result is given in Sec. XI. Sections XII–XIII present consistency checks of the measurement; Sec. XIV describes the study of the asymmetry’s IP dependence. Conclusions are given in Sec. XV.

II. METHOD

The elements of our analysis are described in detail in Ref. [11]. Here, we summarize briefly the method, emphasizing the improvements to our previous procedure. We use two sets of data: (i) inclusive muon data collected with inclusive muon triggers that provide $n^+$ positively charged muons and $n^-$ negatively charged muons, and (ii) like-sign dimuon data, collected with dimuon triggers that provide $N^{++}$ events with two positively charged muons and $N^{--}$ events with two negatively charged muons. If an event contains more than one muon, each muon is included in the inclusive muon sample. Such events constitute about 0.5% of the total inclusive muon sample. If an event contains more than two muons, the two muons with the highest transverse momentum ($p_T$) are selected for inclusion in the dimuon sample. Such events comprise about 0.7% of the total like-sign dimuon sample.

From these data we obtain the inclusive muon charge asymmetry $a$ and the like-sign dimuon charge asymmetry $A$, defined as

\[ a = \frac{n^+ - n^-}{n^+ + n^-}, \]
\[ A = \frac{N^{++} - N^{--}}{N^{++} + N^{--}}. \] (6)

In addition to a possible signal asymmetry $A^b_{a1}$, these asymmetries have contributions from muons produced in kaon and pion decay, or from hadrons that punch through the calorimeter and iron toroids to penetrate the outer muon detector. The charge asymmetry related to muon detection and identification also contributes to $a$ and $A$. These contributions are measured with data, with only minimal input from simulation. The largest contribution by far is from kaon decays. Positively charged kaons have smaller cross sections in the detector material than negatively charged kaons [14], giving them more time to decay. This difference produces a positive charge asymmetry.

We consider muon candidates with $p_T$ in the range 1.5 to 25 GeV. This range is divided into six bins as shown in Table I. The inclusive muon charge asymmetry $a$ can be expressed [11] as

\[ a = \sum_{i=1}^{6} f_i^\mu \{ f_i^{aS}(aS + \delta_i) + f_i^{aK} a_K^i + f_i^{a\pi} a_\pi^i + f_i^{a_p} a_p^i \}, \] (7)

where the fraction of reconstructed muons, $f_i^\mu$, in a given $p_T$ interval $i$ in the inclusive muon sample is given in Table I. The fractions of these muons produced by kaons, pions, and protons in a given $p_T$ interval $i$ are $f_i^{aK}$, $f_i^{a\pi}$, and $f_i^{a_p}$, and their charge asymmetries are $a_K^i$, $a_\pi^i$, and $a_p^i$, respectively. We refer to these muons as “long” or “LL” muons since they are produced by particles traveling long distances before decaying within the detector material. The track of a $L$ muon in the central tracker is dominantly produced by the parent hadron. The charge asymmetry of $L$ muons results from the difference in the interactions of positively and negatively charged particles with the detector material, and is not related to CP violation. The background fraction is defined as $f_i^{bkg} = f_i^{bK} + f_i^{b\pi} + f_i^{b_p}$. The quantity $f_i^b = 1 - f_i^{bkg}$ is the fraction of muons from weak decays of $b$ and $c$ quarks and $\tau$ leptons, and from decays of short-lived mesons ($\phi, \omega, \eta, \rho^0$). We refer to these muons as “short” or “S” muons, since they arise from the decay of particles at small distances from the $p\bar{p}$ interaction point. These particles are not affected by interactions in the detector material, and once muon detection and identification imbalances are removed, the muon charge asymmetry $a_s^b$ must therefore be produced only through CP violation in the underlying physical processes. The quantity $\delta_i$ in Eq. (7) is the charge asymmetry related to muon detection and identification. The background charge asymmetries $a_s^b$,
\( a_i^2 \) and \( a_p^2 \) are measured in the inclusive muon data, and include any detector asymmetry. The \( \delta_i \) therefore accounts only for \( S \) muons and is multiplied by the factor \( \delta_{SS}^f \).

The like-sign dimuon charge asymmetry \( A \) can be expressed\[11\] as

\[
A = F_{SS}A_S + F_{SL}a_S + \sum_{i=1}^{6} F_{\mu}^a((2 - F_{\mu}^b)\delta_i
\]

\[
+ F_Ka_K + F_{\pi}^a + F_p^a) \right). \tag{8}
\]

The quantity \( A_S \) is the charge asymmetry of the events with two like-sign \( S \) muons. The quantity \( F_{SS} \) is the fraction of like-sign dimuon events with two \( S \) muons, \( F_{SL} \) is the fraction of like-sign dimuon events with one \( S \) and one \( L \) muon. We also define the quantity \( F_{LL} \) as the fraction of like-sign dimuon events with two \( L \) muons. The quantity \( F_{\mu}^i \) is the fraction of muons in the \( PT \) interval \( i \) in the like-sign dimuon data. The quantities \( F_x^i \) \((x = K, \pi, p)\) are defined as \( F_x^i = 2N_x/N_i, \) where \( N_x \) is the number of muons produced by kaons, pions, and protons, respectively, in a \( PT \) interval \( i, \) with \( N_i \) being the number of muons in this interval, with the factor of two taking into account the normalization of these quantities per like-sign dimuon event. The quantity \( F_{\mu}^i \) is a sum over muons produced by hadrons:

\[
F_{\mu}^i \equiv F_{K}^i + F_{\pi}^i + F_{p}^i. \tag{9}
\]

We also define \( F_{\mu}^{bkg} \) as

\[
F_{\mu}^{bkg} = \sum_{i=1}^{6} F_{\mu}^i \tag{10}
\]

\[
= F_{SL} + 2F_{LL} - F_{SS}. \tag{11}
\]

The estimated contribution from the neglected quadratic terms in Eq. (8) is approximately \( 2 \times 10^{-5} \), which corresponds to about 5\% of the statistical uncertainty on \( A \).

The asymmetries \( a_S \) and \( A_S \) in Eqs. (7) and (8) are the only asymmetries due to CP violation in the processes producing \( S \) muons, and are proportional to the asymmetry \( A_{SL}^b \):

\[
a_S = c_bA_{SL}^b, \tag{12}
\]

\[
A_S = C_bA_{SL}^b. \tag{12}
\]

The dilution coefficients \( c_b \) and \( C_b \) are discussed in Ref. [11] and in Sec. X below.

Equations (7) – (12) are used to measure the asymmetry \( A_{SL}^b \). The major contributions to the uncertainties on \( A_{SL}^b \) are from the statistical uncertainty on \( A \) and the total uncertainty on \( F_K^i, F_K^b \) and \( \delta_i \). To reduce the latter contributions, we measure the asymmetry \( A_{SL}^b \) using the asymmetry \( A' \), which is defined as

\[
A' \equiv A - a_a. \tag{13}
\]

Since the same physical processes contribute to both \( F_K^i \) and \( F_K^b \), their uncertainties are strongly correlated, and therefore partially cancel in Eq. (13) for an appropriate choice of the coefficient \( a_a \). The contribution from the asymmetry \( A_{SL}^b \), however, does not cancel in Eq. (13) because \( c_b \ll C_b \) [11]. Full details of the measurements of different quantities entering in Eqs. (7) – (12) are given in Ref. [11]. The main improvements in the present analysis are related to muon selection and the measurement of \( F_K^i \) and \( F_K^b \). These modifications are described in Sections III, IV, and V.

### III. MUON SELECTION

The muon selection is similar to that described in Ref. [11]. The inclusive muon and like-sign dimuon samples are obtained from data collected with single and dimuon triggers, respectively. Charged particles with transverse momentum in the range \( 1.5 < p_T < 25 \text{ GeV} \) and with pseudorapidity \( |\eta| < 2.2 \) [15] are considered as muon candidates. The upper limit on \( p_T \) is applied to suppress the contribution of muons from \( W \) and \( Z \) boson decays. To ensure that the muon candidate passes through the detector, including all three layers of the muon system, we require either \( p_T > 4.2 \text{ GeV} \) or a longitudinal momentum component \( |p_z| > 5.4 \text{ GeV} \). Muon candidates are selected by matching central tracks with a segment reconstructed in the muon system and by applying tight quality requirements aimed at reducing false matching and background from cosmic rays and beam halo. The transverse impact parameter of the muon track relative to the reconstructed \( pp \) interaction vertex must be smaller than \( 0.3 \text{ cm} \), with the longitudinal distance from the point of closest approach to this vertex smaller than \( 0.5 \text{ cm} \). Strict quality requirements are also applied to the tracks and to the reconstructed \( pp \) interaction vertex. The inclusive muon sample contains all muons passing the selection requirements. If an event contains more than one muon, each muon is included in the inclusive muon sample. The like-sign dimuon sample contains all events with at least two muon candidates with the same charge. These two muons are required to have an invariant mass greater than \( 2.8 \text{ GeV} \) to minimize the number of events in which both muons originate from the same \( b \) quark.
quark (e.g., $b \to \mu$, $b \to c \to \mu$). Compared to Ref. [11], the following modifications to the muon selection are applied:

- To reduce background from a mismatch of tracks in the central detector with segments in the outer muon system, we require that the sign of the curvature of the track measured in the central tracker be the same as in the muon system. This selection was not applied in Ref. [11], and removes only about 1% of the dimuon events.

- To ensure that the muon candidate can penetrate all three layers of the muon detector, we require either a transverse momentum $p_T > 4.2$ GeV, or a longitudinal momentum component $|p_z| > 5.4$ GeV, instead of $p_T > 4.2$ GeV or $|p_z| > 6.4$ GeV in Ref. [11]. With this change, the number of like-sign dimuon events increases by 25%, without impacting the condition that the muon must penetrate the calorimeter and toroids, as can be deduced from Fig. 1.

- To reduce background from kaon and pion decays in flight, we require that the $\chi^2$ calculated from the difference between the track parameters measured in the central tracker and in the muon system be $\chi^2 < 12$ (for 4 d.o.f.) instead of 40 used in Ref. [11]. With this tighter selection, the number of like-sign dimuon events is decreased by 12%.

Compared to the selections applied in Ref. [11], the total number of like-sign dimuon events after applying all these modifications is increased by 13% in addition to the increase due to the larger integrated luminosity of this analysis.

The muon charge is determined by the central tracker. The probability of charge mis-measurement is obtained by comparing the charge measured by the central tracker and by the muon system and is found to be less than 0.1%.

The polarities of the toroidal and solenoidal magnetic fields are reversed on average every two weeks so that the four solenoid-toroid polarity combinations are exposed to approximately the same integrated luminosity. This allows for a cancellation of first-order effects related to the instrumental asymmetry [16]. To ensure such cancellation, the events are weighted according to the number of events for each data sample corresponding to a different configuration of the magnets’ polarities. These weights are given in Table II. During the data taking of the last part of the sample, corresponding to approximately 2.9 fb$^{-1}$ of $p\bar{p}$ collisions, the magnet polarities were specially chosen to equalize the number of dimuon events with different polarities in the entire sample. The weights in Table II are therefore closer to unity compared to those used in Ref. [11].

### IV. Measurement of $f_K$, $f_\pi$, $f_\rho$

The fraction $f_K$ in the inclusive muon sample is measured using $K^{*0} \to K^+\pi^-\pi^-$ decays, with the kaon identified as a muon (see Ref. [11] for details). The transverse momentum of the $K^+$ meson is required to be in the $p_T$ interval $i$. Since the momentum of a particle is measured by the central tracking detector, a muon produced by a kaon is assigned the momentum of this kaon (a small correction for kaons decaying within the tracker volume is introduced later). The fraction $f_{K^+\pi^-}$ of these decays is converted to the fraction $f_K$ using the relation

$$f_K = \frac{n_i(K^+\pi^-)}{n_i(K^{*+}\to K_S^0\pi^+)} f_{K^+\pi^-},$$

where $n_i(K^+\pi^-)$ and $n_i(K^{*+}\to K_S^0\pi^+)$ are the number of reconstructed $K_S^0 \to \pi^+\pi^-$ and $K^{*+} \to K_S^0\pi^+$ decays, respectively. The transverse momentum of the $K_S^0$ meson is required to be in the $p_T$ interval $i$. We require in

addition that one of the pions from the $K_S^0 \rightarrow \pi^+\pi^-$ decay be identified as a muon. In the previous analysis [11] the production of $K^+$ mesons was studied in a sample of events with an additional reconstructed muon, but we did not require that this muon be associated with a pion from $K_S^0 \rightarrow \pi^+\pi^-$ decay. The fraction of events containing $b$ and/or $c$ quarks was therefore enhanced in the sample, which could result in a bias of the measured fraction $f_K$. This bias does not exceed the systematic uncertainty of $f_K$ and its impact on the $A_b$ value is less than 0.03%. The application of the new requirement ensures that the flavor composition in the selected $K^{*+} \rightarrow K_S^0 \pi^+$ and $K^{*0} \rightarrow K^+\pi^-$ samples is the same and this bias is eliminated.

The selection criteria and fitting procedures used to select and determine the number of $K_S^0$, $K^{*+}$ and $K^{*0}$ events are given in Ref. [11]. As an example, Fig. 2 displays the $\pi^+\pi^-$ invariant mass distribution and the fitted $K_S^0 \rightarrow \pi^+\pi^-$ candidates in the inclusive muon sample, with at least one pion identified as a muon, for $4.2 < p_T(K_S^0) < 5.6$ GeV. Figure 3 shows the $K_S^0\pi^+$ mass distribution and fit to $K^{*+} \rightarrow K_S^0 \pi^+$ candidates for all $K_S^0$ candidates with $4.2 < p_T(K_S^0) < 5.6$ GeV and $480 < M(\pi^+\pi^-) < 515$ MeV. Figure 4 shows the $K^+\pi^-$ mass distribution and the fit result for $K^{*0} \rightarrow K^+\pi^-$ candidates for all kaons with $4.2 < p_T(K^+) < 5.6$ GeV. The $K^+\pi^-$ mass distribution contains contributions from light meson resonances decaying to $\pi^+\pi^-$. The most important contribution comes from the $\rho^0 \rightarrow \pi^+\pi^-$ decay with $\pi \rightarrow \mu$. It produces a broad peak in the mass region close to the $K^{*0}$ mass. The distortions in the background distribution due to other light resonances, which are not identified explicitly, can also be seen in Fig. 4. Our background model therefore includes the contribution of $\rho^0 \rightarrow \pi^+\pi^-$ and two additional Gaussian terms to take into account the distortions around 1.1 GeV. More details of the background description are given in Ref. [11].

The measurement of the fractions $f_\pi$ and $f_\rho$ is also performed using the method of Ref. [11]. The values of $f_K$ and $f_\pi$ are divided by the factors $C_K$ and $C_\pi$, respectively; which take into account the fraction of kaons and pions reconstructed by the tracking system before they decay. These factors are discussed in Ref. [11], and are determined through simulation. Contrary to Ref. [11], this analysis determines these factors separately for kaons and pions. We find the values:

$$C_K = 0.920 \pm 0.006,$$
$$C_\pi = 0.932 \pm 0.006. \quad (15)$$

The uncertainties include contributions from the number of simulated events and from the uncertainties in the momentum spectrum of the generated particles.

The values of $f_K$, $f_\pi$ and $f_\rho$ in different muon $p_T$ bins are shown in Fig. 5 and in Table III. The changes in the muon candidates selection adopted here is the main source of differences relative to the corresponding values in Ref. [11]. The fractions $f_\pi$ and $f_\rho$ are poorly measured in bins 1 and 2, and bins 5 and 6 due to the small number of events, and their contents are therefore combined through their weighted average.
TABLE III: Fractions $f_K$, $f_\pi$, and $f_p$ for different $p_T$ bins.

The bottom row shows the weighted average of these quantities obtained with weights given by the fraction of muons in a given $p_T$ interval, $f^\mu$, in the inclusive muon sample, see Table I. Only statistical uncertainties are given.

V. MEASUREMENT OF $F_K$, $F_\pi$, $F_p$

The quantity $F_K$ is expressed as

$$F_K = R_K f_K,$$  \hfill (16)

where $R_K$ is the ratio of the fractions of muons produced by kaons in like-sign dimuon and in inclusive muon data.

For the $p_T$ interval $i$, $R_K$ is defined as

$$R_{K,i} = \frac{N_i(K \rightarrow \mu)}{n_i(K \rightarrow \mu)} \frac{n_i(\pi \rightarrow \mu)}{N_i(\pi \rightarrow \mu)},$$  \hfill (17)

where $N_i(K \rightarrow \mu)$ and $n_i(K \rightarrow \mu)$ are the number of reconstructed $K$ mesons identified as muons in the like-sign dimuon and in the inclusive muon samples, respectively. The transverse momentum of the $K$ meson is required to be in the $p_T$ interval $i$. The quantities $N_i(\pi \rightarrow \mu)$ and $n_i(\pi \rightarrow \mu)$ are the number of muons in the $p_T$ interval $i$. A multiplicative factor of two is included in Eq. (17) because there are two muons in a like-sign dimuon event, and $F_K$ is normalized to the number of like-sign dimuon events.

In the previous analysis [11], the quantity $F_K$ was obtained from a measurement of the $K^{*0}$ production rate. Presenting it in the form of Eq. (16) also allows the determination of $F_K$ through an independent measurement.
of the fraction of $K_S^0$ mesons in dimuon and in inclusive muon data where one of the pions from $K_S^0 \to \pi^+\pi^-$ decay is identified as a muon. This measurement is discussed below. In addition, Eq. (16) offers an explicit separation of systematic uncertainties associated with $F_K$.

The systematic uncertainty on the fraction $f_K$ affects the two determinations of $A_S^b$ based on Eqs. (7) and (8) in a fully correlated way; therefore, its impact on the measurement obtained using Eq. (13) is significantly reduced. The systematic uncertainty on the ratio $R_K$ does not cancel in Eq. (13). It is estimated directly from a comparison of the values of $R_K$ obtained in two independent channels.

One way to measure $R_K$ is from the fraction of $K^{*0} \to K^+\pi^-$ events in the inclusive muon and like-sign dimuon data,

$$R_{K,i}(K^{*0}) = 2 \frac{N_i(K^{*0} \to \mu)}{n_i(K^{*0} \to \mu)} \frac{n_i(K \to \mu)}{N_i(K \to \mu)}, \quad (18)$$

where $N_i(K^{*0} \to \mu)$ and $n_i(K^{*0} \to \mu)$ are the number of reconstructed $K^{*0} \to K^+\pi^-$ decays, with the kaon identified as a muon in the like-sign dimuon and in the inclusive muon samples, respectively. The transverse momentum of the $K$ meson is required to be in the $p_T$ interval $i$. The measurement using Eq. (18) is based on the assumption

$$\frac{N_i(K^{*0} \to \mu)}{n_i(K^{*0} \to \mu)} = \frac{N_i(K \to \mu)}{n_i(K \to \mu)}, \quad (19)$$

which was validated through simulations in Ref. [11]. The corresponding systematic uncertainty is discussed below.

In Ref. [11], the fractions $F_K^{*0}$ and $f_K^{*0}$ were obtained independently from a fit of the $K^+\pi^-$ invariant mass distribution in the like-sign dimuon and inclusive muon sample, respectively. Figure 6 shows the same mass studies as in Fig. 4, but for the like-sign dimuon sample. The fit in both cases is complicated by the contribution from light meson resonances that decay to $\pi^+\pi^-$, producing a reflection in the $K^+\pi^-$ invariant mass distribution. In addition, the detector resolution is not known a priori and has to be included in the fit. All these complications are reduced significantly or eliminated in the “null-fit” method introduced in Ref. [11], which is used in this analysis to measure the ratio $R_K(K^{*0})$.

In this method, for each $p_T$ interval $i$, we define a set of distributions $P_i(M_{K\pi};\xi)$ that depend on a parameter $\xi$:

$$P_i(M_{K\pi};\xi) = N_i(M_{K\pi}) - \xi \frac{N_i(\mu)}{2n_i(\mu)} n_i(M_{K\pi}), \quad (20)$$

where $N_i(M_{K\pi})$ and $n_i(M_{K\pi})$ are the number of entries in the $p_T$ bin $i$ of the $K^+\pi^-$ invariant mass distributions in the like-sign and inclusive muon samples, respectively. For each value of $\xi$ the number of $K^{*0} \to K^+\pi^-$ decays, $N(K^{*0})$, and its uncertainty, $\Delta N(K^{*0})$, are measured from the $P_i(M_{K\pi};\xi)$ distribution. The value of $\xi$ for which $N(K^{*0}) = 0$ defines $R_{K,i}(K^{*0})$. The uncertainty $\sigma(R_{K,i})$ is determined from the condition that $N(K^{*0}) = \pm \Delta N(K^{*0})$ corresponding to $\xi = R_{K,i}(K^{*0}) \pm \sigma(R_{K,i})$.

The advantage of this method is that the influence of the detector resolution becomes minimal for $N(K^{*0})$ close to zero, and the contribution from the peak background is reduced in $P_i(M_{K\pi};\xi)$ to the same extent as the contribution of $K^{*0}$ mesons, and becomes negligible when $N(K^{*0})$ is close to zero. As an example, Fig. 7 shows the mass distribution $P_i(M_{K\pi};\xi)$ for $\xi = 0.88$, for all kaons with $4.2 < p_T(K^+) < 5.6$ GeV. This distribution is obtained from the distributions shown in Figs. 4 and 6, using Eq. (20). The contributions of both $K^{*0} \to K^+\pi^-$ and $\rho^0 \to \pi^+\pi^-$, as well as any other resonance in the background, disappear. As a result, the fitting procedure becomes more robust, the fitting range can be extended, and the resulting value of $R_K(K^{*0})$ becomes stable under a variation of the fitting parameters over a wider range.

The value of $R_K$ is also obtained from the production rate of $K_S^0$ mesons in the inclusive muon and dimuon samples. We compute $R_{K,i}$ for a given $p_T$ interval $i$, as

$$R_{K,i}(K_S^0) = \frac{N_i(K_S^0 \to \mu)}{n_i(K_S^0 \to \mu)} \frac{n_i(\mu)}{N_i(\mu)}, \quad (21)$$

where $N_i(K_S^0 \to \mu)$ and $n_i(K_S^0 \to \mu)$ are the num-
A dimuon event can be correlated, i.e., in general $N(K^0_S \rightarrow \pi^+ \pi^-)$ decays with one pion identified as a muon in the dimuon and the inclusive muon data, respectively. The correction factor $\kappa_i$ is discussed later in this section. The measurement of $R_{K,i}$ using Eq. (21) assumes isospin invariance and consequent equality of the ratio of production rates in the dimuon and in the inclusive muon samples of $K^+$ and $K^0_S$ mesons, i.e.,

$$\frac{N_i(K^0_S \rightarrow \mu)}{n_i(K^0_S \rightarrow \mu)} = \frac{N_i(K \rightarrow \mu)}{n_i(K \rightarrow \mu)}.$$  

(22)

Since the charged kaon $p_T$ in Eq. (22) is required to be within the $p_T$ interval $i$, the transverse momentum of the $K^0_S$ meson in Eq. (21) is also required to be within the $p_T$ interval $i$. We expect approximately the same number of positive and negative pions from $K^0_S \rightarrow \pi^+ \pi^-$ decays to be identified as a muon. Therefore, we use both like-sign and opposite-sign dimuon events to measure $N_i(K^0_S \rightarrow \mu)$ and we do not use the multiplicative factor of two in Eq. (21). The requirement of having one pion identified as a muon makes the flavor composition in the samples of charged $K \rightarrow \mu$ events and $K^0_S \rightarrow \mu$ events similar.

The charges of the kaon and the additional muon in a dimuon event can be correlated, i.e., in general $N(K^+ \mu^+) \neq N(K^- \mu^+)$. However, the number of $N_i(K^0_S \rightarrow \mu)$ events is not correlated with the charge of the additional muon, i.e., $N(K^0_S \rightarrow \mu^+ \mu^-) = N(K^0_S \rightarrow \mu^- \mu^+)$. Since the ratio $R_{K,i}$ is determined for the sample of like-sign dimuon events, we apply in Eq. (21) the correction factor $\kappa_i$, defined as

$$\kappa_i = \frac{2(N(K^+ \mu^+) + c.c.)}{(N(K^+ \mu^+) + N(K^- \mu^+) + c.c.)},$$  

(23)

to take into account the correlation between the charges of the kaon and muon. The abbreviation “c.c.” in Eq. (23) denotes “charge conjugate states”. The coefficients $\kappa_i$ are measured in data using the events with a reconstructed $K^{*0} \rightarrow K^+ \pi^-$ decay and an additional muon. To reproduce the selection for the dimuon sample [11], the invariant mass of the $K\mu$ system, with the kaon assigned the mass of a muon, is required to be greater than 2.8 GeV. The fitting procedure and selection criteria to measure the number of $K^{*0}$ events are described in Ref. [11]. The values of $\kappa_i$ for different $p_T$ intervals are given in Fig. 8 and in Table IV.

The average muon detection efficiency is different for the inclusive muon and like-sign dimuon samples because of different $p_T$ thresholds used in their triggers. The difference in muon detection efficiency is large for muons with small $p_T$, but it is insignificant for muons above the inclusive-muon trigger threshold. The ratio $N_i(K^0_S \rightarrow \mu)/n_i(K^0_S \rightarrow \mu)$ in Eq. (21) is measured as a function of the transverse momenta of $K^0_S$ mesons, $p_T(K^0_S)$, while the ratio $n_i(\mu)/N_i(\mu)$ is measured in bins of muon $p_T$. Each $p_T(K^0_S)$ bin contains $\pi \rightarrow \mu$ with different $p_T(\pi \rightarrow \mu)$ values. The muon detection efficiency...
therefore does not cancel in Eq. (21), and can affect the measurement of $R_K(K_S^0)$. Figure 9 shows the ratio of $\pi \to \mu$ detection efficiencies in the inclusive muon and dimuon data. To compute this ratio, we select the $K_S^0$ mesons in a given $p_T(K_S^0)$ interval. The $p_T(\pi)$ distribution of pions produced in the $K_S^0 \to \pi^+\pi^-$ decay with a given $p_T(K_S^0)$ is the same in the dimuon and inclusive muon data. Therefore, any difference in this $p_T(\pi \to \mu)$ distribution between dimuon and inclusive muon data is due to the $\pi \to \mu$ detection. We compute the ratio of these $p_T(\pi \to \mu)$ distributions, and normalize it such that it equals unity for $p_T(\pi \to \mu) > 5.6$ GeV. The value of this $p_T$ threshold corresponds to the $p_T$ threshold for single muon triggers. Figure 9 presents the average of the ratios for different $p_T(\mu)$ intervals. The ratio is suppressed for $p_T(\pi \to \mu) < 4.2$ GeV, and is consistent with a constant for $p_T(\pi \to \mu) > 4.2$ GeV. To remove the bias due to the trigger threshold, we measure $R_K(K_S^0)$ for events with $p_T(\pi \to \mu) > 4.2$ GeV. As a result, the ratio $R_K$ is not defined for the first two $p_T$ bins in the $K_S^0$ channel.

The values of $R_K(K^{*0})$ obtained through the null-fit method, for different muon $p_T$ bins, are shown in Fig. 10(a) and in Table V. The values of $R_K(K_S^0)$ are contained in Fig. 10(b) and in Table V. The difference between the values of $R_K$ measured with $K^{*0}$ mesons and with $K_S^0$ mesons is shown in Fig. 11. The mean value of this difference is

$$\Delta R_K = 0.01 \pm 0.05,$$  

and the $\chi^2$/d.o.f. is 1.7/4. We use two independent methods, each relying on different assumptions, to measure the ratio $R_K$ and obtain results that are consistent with each other. The methods are subject to different systematic uncertainties, and therefore provide an important cross-check. As an independent cross-check, the value of $R_K$ obtained in simulation is consistent with that measured in data, see Sec. XIII for details. We take the average of the two channels weighted by their uncertainties as our final values of $R_K$ for $p_T(K) > 4.2$ GeV and use the values measured in the $K^{*0}$ channel for $p_T(K) < 4.2$ GeV. These values are given in Table V and in Fig. 10(c). As we do not observe any difference between the two measurements, we take half of the uncertainty of $\Delta R_K$ as the systematic uncertainty of $R_K$. This corresponds to a relative uncertainty of 3.0% on the value of $R_K$. In our previous measurement [11], this uncertainty was 3.6%, and was based on simulation of the events.

Using the extracted values of $R_K$, we derive the values of $F_K$, $F_\pi$, and $F_p$. The computation of $F_K$ is done using Eq. (16), and we follow the procedure described in Ref. [11] to determine $F_\pi$ and $F_p$. The results are shown in Fig. 12 and in Table VI. The fractions $F_\pi$ and $F_p$ are poorly determined for the lowest and highest $p_T$ because of the small number of events. The content of bins 1 and 2, and bins 5 and 6 are therefore combined.

**VI. SYSTEMATIC UNCERTAINTIES FOR BACKGROUND FRACTIONS**

The systematic uncertainties for the background fractions are discussed in Ref. [11], and we only summarize the values used in this analysis. The systematic uncertainty on the fraction $f_K$ is set to 9% [11]. The systematic uncertainty on the ratio $R_K$, as indicated in Sec. V, is set to half of the uncertainty on $\Delta R_K$ given in Eq. (24).

### Table V: Values of $R_K$ obtained using $K^{*0}$ and $K_S^0$ meson production in different $p_T$ bins. The bottom row shows their average. Only statistical uncertainties are given. The ratio $R_K$ in the $K_S^0$ channel is not measured in the first two bins, see Sec. V.

FIG. 12: (color online). The values of (a) $F_K$, (b) $F_{\pi}$ and (c) $F_p$ in the like-sign dimuon sample as a function of the kaon, pion and proton $p_T$, respectively. The horizontal dashed lines show the mean values.

The systematic uncertainties on the ratios of multiplicities $n_\pi/n_K$ and $n_p/n_K$ in $p\bar{p}$ interactions are set to 4% [17]. These multiplicities are required to compute the quantities $f_\pi$, $f_p$. The ratios $N_\pi/N_K$ and $N_p/N_K$, required to compute the quantities $F_\pi$ and $F_p$ [11] are assigned an additional 4% systematic uncertainty. The values of these uncertainties are discussed in Ref. [11].

VII. MEASUREMENT OF $f_S$, $F_{SS}$

We determine the fraction $f_S$ of $S$ muons in the inclusive muon sample and the fraction $F_{SS}$ of events with two $S$ muons in the like-sign dimuon sample following the procedure described in Ref. [11]. We use the follow-

The asymmetries for other backgrounds are due to the increased statistics and the changes in the muon selection and in the analysis procedure.

VIII. MEASUREMENT OF $a_K$, $a_\pi$, $a_p$, $\delta$

We measure all detector related asymmetries using the methods presented in Ref. [11]. Muons from decays of charged kaons and pions and from incomplete absorption of hadrons that penetrate the calorimeter and reach the muon detectors ("punch-through"), as well as false matches of central tracks to segments reconstructed in the outer muon detector, are considered as detector backgrounds. We use data to measure the fraction of each source of background in both the dimuon and inclusive muon samples, and the corresponding asymmetries. Data are also used to determine the intrinsic charge-detection asymmetry of the D0 detector. Since the interaction length of the $K^+$ meson is greater than that of the $K^-$ meson [14], kaons provide a positive contribution to the asymmetries $A$ and $a$. The asymmetries for other backgrounds (pions, protons and falsely reconstructed tracks) are at least a factor of ten smaller.

The results for the asymmetries $A_{K}$, $a_\pi$, and $a_p$ in different muon $p_T$ bins are shown in Fig. 13 and Table VII. The asymmetries $a_\pi$ and $a_p$ are poorly measured in the first and last bins due to the small number of events. The content of bins 1 and 2, and bins 5 and 6 are therefore combined.

The small residual reconstruction asymmetry $\delta_i$ is measured using a sample of $J/\psi \rightarrow \mu^+\mu^-$ decays reconstructed from two central detector tracks, with at least one matching a track segment in the muon detector. The values of $\delta_i$ obtained as a function of muon $p_T$ are given in Table VIII and are shown in Fig. 14. The weighted averages for the residual muon asymmetry in the inclusive muon and the like-sign dimuon samples, calculated using weights given by the fraction of muons in each $p_T$ interval $K_i (F_i)$ in the inclusive muon (dimuon) sample, are given by

$$\delta \equiv \sum_{i=1}^{6} f_i \delta_i = (−0.088 ± 0.023)\%,$$

$$\Delta \equiv \sum_{i=1}^{6} F_i \delta_i = (−0.132 ± 0.019)\%,$$

where only the statistical uncertainties are given. The correlations among different $\delta_i$ are taken into account in the uncertainties in Eqs. (27) and (28).
To measure the weights for the different processes producing 5 muons, we correct the momentum distribution of generated $b$ hadrons to match that in the data used in this analysis. The determined weights [17] are given in Table XI.

The uncertainty on the weights for the different processes contains contributions from the uncertainty in the momentum of the generated $b$ hadrons and from the uncertainties in $b$-hadron branching fractions. The difference in the weights with and without the momentum correction contributes to the assigned uncertainties. Additional contributions to the uncertainties on the weights derive from the uncertainties on the inclusive branching fractions.

### IX. CORRECTIONS FOR BACKGROUND ASYMMETRIES

The corrections for the background and detector contributions to the measured raw asymmetries $A$ and $A$ are obtained combining the results from Tables I, III, VI, and VII, and summarized in Tables IX and X. The values in the bottom row of these tables are computed by averaging the corresponding quantities with weights given by the fraction of muons in each $p_T$ interval, $f_\mu$, in the inclusive muon (dimuon) sample, see Eqs. (7) and (8).

We use the mean values for $f_\pi$, $F_\pi$, $f_\rho$, $F_\rho$, $a_x$, and $a_p$ in bins 1 and 2, and in bins 5 and 6, as the number of events for those bins are not sufficient to perform separate measurements.

### X. COEFFICIENTS $c_0$ AND $C_0$

The dilution coefficients $c_0$ and $C_0$ in Eq. (12) are obtained through simulations using the method described in Ref. [11]. Both coefficients depend on the value of the mean mixing probability, $\chi_0$. We use the value obtained at LEP as averaged by HFAG [3] for this measurement

$$\chi_0(^{\text{HFAG}}) = 0.1259 \pm 0.0042.$$

To measure the weights for the different processes producing 5 muons, we correct the momentum distribution of generated $b$ hadrons to match that in the data used in
TABLE XII: Contribution of different background sources to the observed asymmetry in the inclusive muon and like-sign dimuon samples. Only statistical uncertainties are given.

fractions $B \to \mu X$, $B \to cX$ and $B \to cX$ [14]. We assign an additional uncertainty of 15% to the weights $w_5$ and $w_6$ for uncertainties on the cross sections for $c\bar{c}$ and $b\bar{b}c\bar{c}$ production.

The resulting $c_5$ and $C_b$ coefficients are found to be

$$c_b = +0.061 \pm 0.007,$$

$$C_b = +0.474 \pm 0.032.$$  \hspace{1cm} (31)

XI. ASYMMETRY $A_{\text{sl}}^b$

The results obtained in Secs. IV–X are used to measure the asymmetry $A_{\text{sl}}^b$ following the procedure of Ref. [11]. Using $2.041 \times 10^5$ muons in the inclusive muon sample and $6.019 \times 10^6$ events in the like-sign dimuon sample we obtain the following values for the uncorrected asymmetries $a$ and $A$:

$$a = (+0.688 \pm 0.002)\%,$$

$$A = (+0.126 \pm 0.041)\%.$$  \hspace{1cm} (33)

The difference between these values and those in Ref. [11] are due to increased statistics and the changes in the muon selection. The contributions from different background sources to the observed asymmetries $a$ and $A$ are summarized in Table XII.

The asymmetry $A_{\text{sl}}^b$, extracted from the asymmetry $a$ of the inclusive muon sample using Eqs. (7) and (30), is

$$A_{\text{sl}}^b = (-1.04 \pm 1.30 \text{ (stat)} \pm 2.31 \text{ (syst)})\%.$$  \hspace{1cm} (34)

The contributions to the uncertainty are given in Table XIII. Figure 15(a) shows a comparison of the asymmetry $a$ and the background asymmetry, $a_{\text{bkg}} = f_S\delta + f_Ka_K + f_\pi a_\pi + f_\rho a_\rho$, as a function of muon $p_T$. There is excellent agreement between these two quantities, with $\chi^2$/d.o.f. = 0.8/6 for their difference. Figure 15(b) shows the value of $f_Sa_S = a - a_{\text{bkg}}$, which is consistent with zero. The values $a$ and $a_{\text{bkg}}$ are given in Table XIV. This result agrees with the expectation that the value of the asymmetry $a$ is determined mainly by the background, as the contribution from $A_{\text{sl}}^b$ is strongly suppressed by the factor of $c_b = 0.061 \pm 0.007$. The consistency of $A_{\text{sl}}^b$ with zero in Eq. (34) and the good description of the charge asymmetry $a$ for different values of muon $p_T$ shown in Fig. 15 constitute important tests of the validity of the background model and of the method of analysis discussed in this Article.

The second measurement of the asymmetry $A_{\text{sl}}^b$, obtained from the uncorrected asymmetry $A$ of the like-sign dimuon sample using Eqs. (8), (30) and (31), is

$$A_{\text{sl}}^b = (-0.808 \pm 0.202 \text{ (stat)} \pm 0.222 \text{ (syst)})\%.$$  \hspace{1cm} (35)

where we take into account that both $A_S$ and $A_\rho$ in Eq. (8) are proportional to $A_{\text{sl}}^b$, and that $F_{SS}C_\rho + F_{SL}C_\rho = 0.342 \pm 0.028$. The contributions to the uncertainty of $A_{\text{sl}}^b$ for this measurement are also listed in Table XIII.

The measurement of the asymmetry $A_{\text{sl}}^b$ using the linear combination given in Eq. (13) is performed following the procedure described in Ref. [11]. We select the value of the parameter $\alpha$ that minimizes the total uncertainty on the $A_{\text{sl}}^b$ measurement. Appendix A gives more details on this method of combination. All uncertainties in

TABLE XIII: Sources of uncertainty on $A_{\text{sl}}^b$ from Eqs. (34), (35), and (36). The first nine rows contain statistical uncertainties, while the next four rows reflect contributions from systematic uncertainties.

Table XIII, except the statistical uncertainties on \( \alpha \), \( A \),
and \( R_{K} \), are treated as fully correlated. This leads to
\( \alpha = 0.89 \), and the corresponding value of the asymmetry
\( A_{sl}^{b} \) is
\[
A_{sl}^{b} = (-0.787 \pm 0.172 \text{ (stat)} \pm 0.093 \text{ (syst)})\%.
\]
This value is used as the final result for \( A_{sl}^{b} \). It differs by
3.9 standard deviations from the standard model prediction of \( A_{sl}^{b} \)
given in Eq. (5). The different contributions to the total uncertainty on \( A_{sl}^{b} \) in Eq. (36) are listed in
Table XIII.

The measured value of \( A_{sl}^{b} \) places a constraint on the
charge asymmetries \( a_{sl}^{d} \) and \( a_{sl}^{s} \). The asymmetry \( A_{sl}^{b} \) is a
linear combination of the semi-leptonic charge asymmetries
from \( B^{0} \) and \( B_{s}^{0} \) meson decays [2]. The coefficients
\( C_{s} \) and \( C_{d} \) in Eq. (2) depend on the mean mixing probability
and the production rate of \( B^{0} \) and \( B_{s}^{0} \) mesons. We use the latest measurements of these quantities from
LEP as averaged by HFAG [3]
\[
\begin{align*}
\chi_{0}(\text{HFAG}) & = 0.1259 \pm 0.0042, \\
\mu_{d}(\text{HFAG}) & = 0.403 \pm 0.009, \\
\mu_{s}(\text{HFAG}) & = 0.103 \pm 0.009,
\end{align*}
\]
and find the values given in Eq. (4).

Figure 16 presents the measurement in the \( (a_{sl}^{d}, a_{sl}^{s}) \)
plane together with the existing direct measurements of \( a_{sl}^{d} \)
from the \( B \) factories [3] and the independent D0 measure-
ment of \( a_{sl}^{s} \) in \( B_{s}^{0} \to \mu \nu X \) decays [19]. All measure-
ments are consistent.

The quantity \( A_{res} \) defined as
\[
A_{res} \equiv (A - \alpha \alpha) - (A_{bkg} - \alpha a_{bkg}) \quad (40)
\]
is the residual charge asymmetry of like-sign dimuon events
after subtracting all background contributions from the raw charge asymmetry. This quantity does not depend
on the interpretation in terms of the charge asymmetry of
semi-leptonic decays of \( B \) mesons. We obtain
\[
A_{res} = (-0.246 \pm 0.052 \text{ (stat)} \pm 0.021 \text{ (syst)})\% \quad (41)
\]
The measured value of \( A_{res} \) differs by 4.2 standard deviations
from the standard model prediction
\[
A_{res}(\text{SM}) = (-0.009 \pm 0.002)\% \quad (42)
\]

XII. CONSISTENCY CHECKS

To study the stability of the result, we repeat this
measurement with modified selections, and with subsets
of the available data. The only difference compared to Ref. [11] is Test D, where we applied a stronger criterion on the muon IP, following the suggestion of Ref. [18]. In all tests the modified selections were applied to all muons. For completeness, we give the full list of tests performed:

- Test A1: Using only the part of the data sample corresponding to the first 2.8 fb$^{-1}$.
- Test A2: Using only the part of the data sample corresponding to the previous measurement with 6.1 fb$^{-1}$ [11].
- Test A3: Using only the part of the data sample corresponding to the last 2.9 fb$^{-1}$.
- Test B: In addition to the reference muon selections [11], we require at least three hits in the muon wire chambers (layers B or C), and lower the $\chi^2$ requirement for the fit to a track segment reconstructed in the muon detector.
- Test C: Since background muons are mainly produced by decays of kaons and pions, their track parameters measured in the central tracker and by the muon system can differ. The background fraction therefore depends strongly on the $\chi^2$ of the difference between these two measurements. The requirement on this $\chi^2$ is changed from 12 to 4.
- Test D: The maximum value of the IP is changed from 0.3 to 0.012 cm. This test is also sensitive to possible contamination from cosmic-ray muons.
- Test E: Using low-luminosity data with fewer than three interaction vertices.
- Test F: Using events corresponding to only two of four possible configurations for the magnets, with identical solenoid and toroid polarities.
- Test G: Changing the minimum requirement on the invariant mass of the two muons from 2.8 GeV to 12 GeV.
- Test H: Using the same muon $p_T$ requirement, $p_T > 4.2$ GeV, for the full detector acceptance.
- Test I: Requiring the muon $p_T$ to be $p_T < 7.0$ GeV.
- Test J: Requiring the azimuthal angle $\phi$ of the muon track to be in the range $0 < \phi < 4$ or $5.7 < \phi < 2\pi$. This selection excludes muons with reduced muon identification efficiency in the region of the support structure of the detector.
- Test K: Requiring the muon $\eta$ to be in the range $|\eta| < 1.6$. This test is sensitive to possible contamination from muons associated with beam halos.
- Test L: Requiring the muon $\eta$ to have $|\eta| < 1.2$ or $1.6 < |\eta| < 2.2$.

- Test M: Requiring the muon $\eta$ to be in the range $|\eta| < 0.7$ or $1.2 < |\eta| < 2.2$.
- Test N: Requiring the muon $\eta$ to be in the range $0.7 < |\eta| < 2.2$.
- Test O: Using like-sign dimuon events that pass at least one single muon trigger, while ignoring the requirement for a dimuon trigger.
- Test P: Using like-sign dimuon events passing both single muon and dimuon triggers.

A summary of these studies is presented in Tables XV and XVI. The last row, denoted as “Significance”, gives the absolute value of the difference between the reference result (column Ref) and each modification, divided by its uncertainty, taking into account the overlap in events between the reference and test samples. Both statistical and systematic uncertainties are used in the calculation of the significance of the difference. The $\chi^2$ of these tests defined as the sum of the square of all significances $\chi^2 = \sum (d_i - a_i)^2 / a_i^2$, where $d_i$ is the number of observed events and $a_i$ is the number of expected events.

We also compare the dependence on the muon pseudo-rapidity $\eta(\mu)$ of the observed and expected charge asymmetry in the inclusive muon sample. We repeat the analysis procedure, but measure all background contributions as a function of $|\eta(\mu)|$. The result of this comparison is shown in Fig. 17. The dependence on $|\eta(\mu)|$ is correctly described by the background asymmetry. There is good agreement between these two quantities, with a $\chi^2$/d.o.f. = 2.8/4. This is consistent with our expectation that the contribution of $A_{1b}^B$ in the inclusive muon charge asymmetry is overwhelmed by background.

Figure 18 shows the observed and expected uncorrected like-sign dimuon charge asymmetry as a function of the dimuon invariant mass. The expected asymmetry is computed using Eq. (8) and the measured parameters of sample composition and asymmetries. As in Ref. [11], we compare the expected uncorrected asymmetry using two assumptions for $A_{1b}^B$. In Fig. 18(a) the observed asymmetry is compared to the expectation for the SM value of $A_{1b}^B(SM) = -0.028\%$, while Fig. 18(b) shows the expected asymmetry for $A_{1b}^B = -0.787\%$. Large discrepancies between the observed and expected asymmetries can be observed for $A_{1b}^B = A_{1b}^B(SM)$, while good agreement is obtained for the measured $A_{1b}^B$ value corresponding to Eq. (36). The observed asymmetry changes as a function of dimuon invariant mass, and the expected asymmetry tracks this effect when $A_{1b}^B = -0.787\%$. This dependence of the asymmetry on invariant mass of the muon pair is a function of the production mechanism of the particles involved and of their decays. The agreement between the observed and expected asymmetries indicates that the physics leading to the observed asymmetry can be described by contributions from the background and from decays of $b$ hadrons.

</table>

We also measure the mean mixing probability using the ratio of like-sign and opposite-sign dimuon events. The background contribution in both samples is obtained using the method presented in this Article. The measured mean mixing probability is found to be consistent with the world average value [3].

We conclude that our method of analysis provides a consistent description of the dimuon charge asymmetry for a wide range of input parameters, as well as for significantly modified selection criteria.

XIII. COMPARISON WITH SIMULATION

The measurement of the background fractions is based on data, and the input from simulation is limited to the ratio of multiplicities $n_{\pi}/n_K$ and $n_{\mu}/n_K$ in $pp$ interactions [11]. Nevertheless, it is instructive to compare the results obtained in data and in simulation. Such a comparison is shown in Table XVII. The simulation used in this analysis is described in Ref. [11]. All quantities measured in simulation are obtained using the information on the generated processes. All uncertainties in the second and third columns are statistical. The difference between the values obtained in data and simulation is given in the fourth column and includes the systematic uncertainties. The agreement between the measured and simulated quantities is satisfactory. The excellent agreement between the mean values of $R_K$, which is one of the most essential quantities of this measurement and for which many systematic uncertainties cancel, is especially notable:

$$R_K(\text{data}) = 0.856 \pm 0.020 \ (\text{stat}) \pm 0.026 \ (\text{syst}),$$

$$R_K(\text{MC}) = 0.901 \pm 0.086 \ (\text{MC stat}).$$

This comparison provides support for the validity of the presented measurement.

XIV. DEPENDENCE OF ASYMMETRY $A_b^b$ ON MUON IMPACT PARAMETER

The asymmetry $A_b^b$ is produced by muons from direct semi-leptonic decays of $b$ quarks. A distinctive feature of these muons is the large impact parameter of their trajectories with respect to the primary vertex [12, 18]. The simulation shows that the dominant source of background from $L$ muons corresponds to charged hadrons produced in the primary interactions that then decay to muons, and the tracks of such muons have small impact parameters if the decay is outside the tracking volume. Figure 19 shows the muon IP distribution in data and in simulation. The shaded histogram shows the contribution from...
L muons in simulation, which decreases significantly for increasing values of the muon IP. The background can therefore be significantly suppressed by selecting muons with large impact parameter.

To verify the origin of the observed charge asymmetry, we perform several complementary measurements. We require the muon IP to be larger or smaller than 120 \( \mu m \). For events in the like-sign dimuon sample, we require that both muons satisfy these conditions. These measurements are denoted as \( IP_{>120} \) and \( IP_{<120} \), respectively. The selected threshold of 120 \( \mu m \) can be compared with the spread in the crossing point of the colliding beams in the Tevatron collider, and with the precision of \( p\bar{p} \) vertex reconstruction, which are about 30 \( \mu m \) and 15 \( \mu m \), respectively, in the plane perpendicular to the beam axis. The chosen value of 120 \( \mu m \) gives the minimal uncertainty on \( a_{\text{bkg}}^b \) and \( a_{\text{bkg}}^s \) defined in Eq. (2).
In total, $0.356 \times 10^9$ muons in the inclusive muon sample and $0.714 \times 10^6$ events in the like-sign dimuon sample are selected for the $IP_{>120}$ measurement. Events are subject to the same analysis as for the entire sample, except that the ratio $R_K(K^0\bar{\nu})$ is not used because of insufficient $K^0_d \rightarrow \pi^+\pi^-$ decays in the dimuon sample. Background asymmetries should not depend on the muon IP, and we verified that the difference in kaon asymmetry for the whole sample and the $IP_{>120}$ events agree: $\alpha_K(IP_{>120}) - \alpha_K(\text{all}) = (-1.6 \pm 1.5)\%$. We therefore use the values given in Tables VII and VIII. All other measured quantities are given in Table XVIII. The background fractions are strongly suppressed in the $IP_{>120}$ sample, and their influence on the measurement of $A_{sl}^0$ is significantly smaller. Using these values, we obtain for the inclusive muon sample

$$A_{sl}^0(IP_{>120}) = (-0.422 \pm 0.240 \, \text{(stat)} \pm 0.121 \, \text{(syst)})\%,$$  

and for the like-sign dimuon sample

$$A_{sl}^0(IP_{>120}) = (-0.818 \pm 0.342 \, \text{(stat)} \pm 0.067 \, \text{(syst)})\%.$$  

We obtain the final value of $A_{sl}^0(IP_{>120})$ using the linear combination of Eq. (13), and select the value of $\alpha$ to minimize the total uncertainty on $A_{sl}^0$, which corresponds to $\alpha = -9.29$. The combination for a negative value of $\alpha$ is equivalent to the weighted average of Eqs. (44) and (45) taking into account the correlation of uncertainties (see Appendix A for more details). The corresponding asymmetry $A_{sl}^0$ is found to be

$$A_{sl}^0(IP_{>120}) = (-0.579 \pm 0.210 \, \text{(stat)} \pm 0.094 \, \text{(syst)})\%.$$  

The contributions to the uncertainties in Eqs. (44 – 46) are given in Table XIX.

From the known frequencies of oscillations, $\Delta M_q/2\pi$ ($q = d, s$), the period of oscillation for the $B^0$ meson is many times longer than its lifetime so that the mixing probability of $B^0$ mesons effectively increases with long decay lengths and large impact parameters. The $B^0_d$ meson oscillates a number of times within its lifetime so that it is “fully mixed” for any appreciable impact parameter requirement. As a result, the fraction of $B^0$ mesons that have oscillated into the other flavor is increased in the sample with large muon impact parameter. This behavior is demonstrated in Fig. 20, which shows the normalized IP distributions for muons produced in oscillating $\pi$-mesons effectively increases with long

$$\text{IP}_{>120} \text{ samples}$$

Table XIX: Sources of uncertainty on $A_{sl}^0(IP_{>120})$ in Eqs. (44), (45), and (46). The first nine rows contain statistical uncertainties, and the next four rows contain systematic uncertainties.

</table>

The measurement of $IP_{<120}$ is performed using $1.687 \times 10^6$ muons in the inclusive muon sample and $2.857 \times 10^6$ muons in the inclusive muon sample and 2 muons in the like-sign dimuon sample.
events in the like-sign dimuon sample. Exactly the same procedure is applied as for the main measurement, using the background and muon reconstruction asymmetries given in Tables VII and VIII. All other quantities are given in Table XVIII. The background fractions are significantly increased in the samples with small muon IP, thereby increasing the uncertainties related to the background description (Table XX).

Using these values we obtain from the inclusive muon sample

\[ A_{31}^b(IP_{<120}) = (-1.65 \pm 2.77 \text{ (stat)} \pm 4.96 \text{ (syst)})\% . \]  

(49)

and from the like-sign dimuon sample

\[ A_{31}^b(IP_{<120}) = (-1.17 \pm 0.44 \text{ (stat)} \pm 0.59 \text{ (syst)})\% . \]  

(50)

The measurement using the linear combination given in Eq. (13) is performed with \( \alpha = +1.27 \), which minimizes the total uncertainty on \( A_{31}^b \). The value of \( A_{31}^b \) is found to be

\[ A_{31}^b(IP_{<120}) = (-1.14 \pm 0.37 \text{ (stat)} \pm 0.32 \text{ (syst)})\% . \]  

(51)

The mean mixing probability \( \chi_d \) in the \( IP_{<120} \) sample obtained in simulation is found to be

\[ \chi_d(IP_{<120}, MC) = 0.084 \pm 0.002, \]  

(52)

and the coefficients \( C_d \) and \( C_s \) in Eq. (2) for the \( IP_{<120} \) selection are

\[ C_d(IP_{<120}) = 0.397 \pm 0.022, \]

\[ C_s(IP_{<120}) = 0.603 \pm 0.022. \]  

(53)

The measurements with \( IP_{<120} \) and \( IP_{>120} \) use independent data samples, and the dependence of \( A_{31}^b \) on \( a_3^d \) and \( a_3^s \) is different for the \( IP_{<120} \) and \( IP_{>120} \) samples. The measurements given in Eqs. (46) and (51) can therefore be combined to obtain the values of \( a_3^d \) and \( a_3^s \), taking into account the correlation among different sources of uncertainty. All uncertainties in Tables XIX, XX, except the statistical uncertainties on \( a, A, f_K, R_K, P(\pi \rightarrow \mu)/P(K \rightarrow \mu) \), and \( P(p \rightarrow \mu)/P(K \rightarrow \mu) \) are treated as fully correlated. The values of \( a_3^d \) and \( a_3^s \) extracted are

\[ a_3^d = (-0.12 \pm 0.52)\%, \]

\[ a_3^s = (-1.81 \pm 1.06)\%. \]  

(54)

The correlation \( \rho_{ds} \) between these two quantities is

\[ \rho_{ds} = -0.799. \]  

(55)

The uncertainty on \( a_3^d \) and \( a_3^s \) obtained in this study is comparable with that obtained from the direct measurements. Figure 21 presents the results of the IP study in the \((a_3^d, a_3^s)\) plane together with the result (36) of the \( A_{31}^b \) measurement using all like-sign dimuon events. The ellipses represent the 68% and 95% two-dimensional C.L. regions, respectively, of \( a_3^d \) and \( a_3^s \) values obtained from the measurements with IP selections.

We also performed four additional measurements with IP thresholds of 50 \( \mu m \) and 80 \( \mu m \). They are denoted as \( IP_{<50} \), \( IP_{>50} \), \( IP_{<80} \), and \( IP_{>80} \), respectively. The input quantities for these measurements are presented in Tables XXI and XXII. The \( A_{31}^b \) values in the inclusive and like-sign dimuon samples and their combinations are given in Table XXIII. The mean mixing probability \( \chi_d \) for all these measurements is obtained through simulation. The results are presented in Table XXIV, together with the corresponding coefficients \( C_d \) and \( C_s \).

As for the combinations of the \( IP_{<120} \) and \( IP_{>120} \) samples, the measurements with \( IP_{<50} \) and \( IP_{>50} \) samples, as well as with \( IP_{<80} \) and \( IP_{>80} \) samples, can be combined to determine the values of \( a_3^d \) and \( a_3^s \) (Table XXV). The measurements with different IP thresholds are consistent with each other within two standard deviations.
taking into account the correlation between the uncertainties.

We conclude that the observed dependence of the like-sign dimuon charge asymmetry on muon IP is consistent with the hypothesis that it has its origin from semileptonic $b$-hadron decays. The contributions of $a^d_{sl}$ and $a^s_{sl}$ to $A^b_{sl}$ can be determined separately by dividing the sample according to the muon IP, although the uncertainties on the values of $a^d_{sl}$ and $a^s_{sl}$ do not allow for the definitive conclusion that the deviation of $A^b_{sl}$ from its SM prediction is dominated from the $a^d_{sl}$ asymmetry.

**XV. CONCLUSIONS**

We have presented an update to the previous measurement [11] of the anomalous like-sign dimuon charge asymmetry $A^b_{sl}$ with 9.0 fb$^{-1}$ of integrated luminosity. The analysis has improved criteria for muon selection, which provide a stronger background suppression and increase the size of the like-sign dimuon sample. A more accurate measurement of the fraction of kaons that produce muons in the inclusive muon sample ($f_K$), and an additional measurement of the ratio of such yields in like-sign dimuon to inclusive muon data ($R_K = F_K/f_K$) using $K^0 \rightarrow \pi^+\pi^-$ decay have been performed. This provides better precision of $R_K$, and an independent estimate of the systematic uncertainty on this quantity. The value of the like-sign dimuon charge asymmetry $A^b_{sl}$ in semileptonic $b$-hadron decays is found to be

$$A^b_{sl} = (-0.787 \pm 0.172 \text{ (stat)} \pm 0.093 \text{ (syst)}) \%.$$  \hfill (56)

This measurement disagrees with the prediction of the standard model by 3.9 standard deviations and provides evidence for anomalously large $CP$ violation in semileptonic neutral $B$ decay. The residual charge asymmetry of like-sign dimuon events after taking into account

![FIG. 21: (color online). Measurements of $A^b_{sl}$ with different muon IP selections in the $(a^d_{sl}, a^s_{sl})$ plane. The bands represent the ±1 standard deviation uncertainties on each independent measurement. The ellipses represent the 68% and 95% two-dimensional C.L. regions, respectively, of $a^d_{sl}$ and $a^s_{sl}$ values obtained from the measurements with IP selections.](image-url)
all background sources is found to be

$$A_{\text{res}} = (-0.246 \pm 0.052 \text{ (stat)} \pm 0.021 \text{ (syst)})\%.$$  \hspace{1cm} (57)

It differs by 4.2 standard deviations from the standard model prediction.

Separation of the sample by muon impact parameter allows for separate extraction of $a^d_{s1}$ and $a^s_{s1}$. We obtain

$$a^d_{s1} = (-0.12 \pm 0.52)\%,$$

$$a^s_{s1} = (-1.81 \pm 1.06)\%.$$  \hspace{1cm} (58)

The correlation $\rho_{ds}$ between these two quantities is

$$\rho_{ds} = -0.799.$$  \hspace{1cm} (59)

The uncertainties on $a^d_{s1}$ and $a^s_{s1}$ do not allow for the definitive conclusion that $a^s_{s1}$ dominates the value of $A^{b}_{d1}$.

Our results are consistent with the hypothesis that the anomalous like-sign dimuon charge asymmetry arises from semi-leptonic $b$-hadron decays. The significance of the difference of this measurement with the SM prediction is not sufficient to claim observation of physics beyond the standard model, but it has grown compared to our previous measurement with a smaller data sample.

## Appendix A: Combination of two measurements using $\alpha$ scan

In this analysis, the value of $A^{b}_{d1}$ is obtained from the linear combination in Eq. (13). The parameter $\alpha$ is selected to minimize the total uncertainty on $A^{b}_{d1}$, taking into account the correlation among different contributions to the uncertainty on $A^{b}_{d1}$. This procedure is equivalent to the standard procedure of taking a weighted average.

To demonstrate this, we consider a model in which we obtain the quantity $x$ using two measurements $a$ and $A$. Suppose that $a$ and $A$ depend linearly on $x$:

$$a = kx + b,$$

$$A = Kx + B,$$  \hspace{1cm} (A1)

where $k$, $K$, $b$, and $B$ are parameters determined in the analysis, and correspond to the measurement of $A^{b}_{d1}$. Using the measurements of $a$ and $A$, we obtain two estimates of $x$:

$$x_1 = (a - b)/k,$$

$$x_2 = (A - B)/K.$$  \hspace{1cm} (A2)
We denote the uncertainties on $x_1$ and $x_2$ as $\sigma_1$ and $\sigma_2$, respectively.

Consider the case where the measurements of $a$ and $A$, as well as the uncertainties $\sigma_1$ and $\sigma_2$, are statistically independent. In this case, the value of $x$ can be obtained as a weighted average:

$$
\begin{align*}
  x & = \frac{(w_1 x_1 + w_2 x_2)}{w}, \\
  w_i & = 1/\sigma_i^2, \; i = 1, 2, \\
  w & = 1/\sigma_1^2 + 1/\sigma_2^2.
\end{align*}
$$

(A3)

Consider another estimate of $x$ using the difference

$$
A' = A - \alpha a,
$$

(A4)

where $\alpha$ is a free parameter. The value of $x$ obtained from Eq. (A4) is

$$
x = \frac{(A - B) - \alpha(a - b)}{K - \alpha k}.
$$

(A5)

Provided that the two measurements $a$ and $A$, as well as the uncertainties $\sigma_1$ and $\sigma_2$ are statistically independent, the minimal uncertainty on $x$ is obtained for

$$\alpha_{\text{min}} = -(K\sigma_2^2)/(k\sigma_1^2).
$$

(A6)

The central value and uncertainty on $x$ obtained from Eq. (A5), with $\alpha = \alpha_{\text{min}}$, are exactly the same as the central value and uncertainty obtained from the weighted average (A3). This case is similar to the combination (46) of the two measurements with $IP > 120 \mu m$ that have reduced correlations. The coefficient $\alpha$ in this case is negative, and its value depends on the uncertainties $\sigma_1$ and $\sigma_2$.

Consider another extreme case, where $k = 0$ and $B$ is fully correlated with $b$, e.g., $B = Cb$, where $C$ is a coefficient. In this case, the value of $x$ obtained from Eq. (A5) is equal to

$$
x = \frac{A - aa - (C - \alpha)b}{K}.
$$

(A7)

Provided that $\sigma(a) \ll \sigma(A)$, the minimal uncertainty of $x$ is obtained for $\alpha_{\text{min}} = C$. This case corresponds to the measurement of Eq. (36) with the full data sample. The value of $\alpha_{\text{min}}$ is positive for $C > 0$.

These two examples demonstrate that the method of the $\alpha$ scan used in this analysis is equivalent to the weighted average of two measurements, taking into account the correlation among different uncertainties.

---

[1] Charge conjugate states are implied throughout this Article.
[12] The impact parameter is defined here as the distance of closest approach to a given vertex of the projection of a particle’s trajectory on the plane perpendicular to the direction of the beam.
[15] The D0 detector utilizes a right-handed coordinate system with the $z$ axis pointing in the direction of the proton beam and the $y$ axis pointing upwards. The azimuthal angle is defined in the $xy$ plane measured from the $x$ axis. The pseudorapidity is defined as $\eta \equiv -\ln[\tan(\theta/2)]$, where $\theta$ is the polar angle with respect to the proton beam direction.
[17] The notation and definition of all quantities are given in Ref. [11].
