ABSTRACT: Multiple Sclerosis (MScl) is a neurodegenerative disease of the CNS, associated with chronic neuroinflammation. Cerebrospinal fluid (CSF), being in closest interaction with CNS, was used to profile neuroinflammation to discover disease-specific markers. We used the commonly accepted animal model for the neuroinflammatory aspect of MScl: the experimental autoimmune/allergic encephalomyelitis (EAE). A combination of advanced 1H NMR spectroscopy and pattern recognition methods was used to establish the metabolic profile of CSF of EAE-aﬀected rats (representing neuroinflammation) and of two control groups (healthy and peripherally inﬂamed) to detect speciﬁc markers for early neuroinflammation. We found that the CSF metabolic proﬁle for neuroinflammation is distinct from healthy and peripheral inﬂammation and characterized by changes in concentrations of metabolites such as creatine, arginine, and lysine. Using these disease-speciﬁc markers, we were able to detect early stage neuroinflammation, with high accuracy in a second independent set of animals. This conforms the predictive value of these markers. These ﬁndings from the EAE model may help to develop a molecular diagnosis for the early stage MScl in humans.

KEYWORDS: ANOVA-PCA, cerebrospinal ﬂuid, EAE model, 1H NMR spectroscopy, pattern recognition, PLS-DA

INTRODUCTION

Multiple Sclerosis (MScl) is a chronic progressive inflammatory, presumably autoimmune, disease of the human central nervous system (CNS) in which the fatty myelin sheaths that surround the axons of the neurons of the brain and spinal cord are damaged, leading to demyelination.¹ MScl is one of the most common neurological diseases and usually starts in early adulthood and progresses to serious neurological disability. It has an enormous impact on the health care system and economy of different countries. Currently, MScl aﬀects approximately one million people worldwide, and the total cost of MScl has been estimated at 12.5 billion € per year.²,³

The animal model of MScl, the experimental autoimmune/allergic encephalomyelitis (EAE) model,⁴–⁹ has become an important tool for understanding the human disease. EAE is a cell-mediated experimental autoimmune disorder of the CNS and shares its clinical expression and pathological picture with that of MScl. For instance, the Lewis rats in which neuroinflammation is induced by means of myelin basic protein (MBP), as in our study here, display a typical disease curve resembling that of the beginning of MScl relapsing-remitting type (RR-MScl). RR-MScl is the most common type of the early stage of MScl. EAE is therefore a useful model for the neuroinflammatory aspect of MScl. Note that EAE does not mimic neurodegeneration and widespread demyelination seen in MScl.¹⁰ In EAE, demyelination might be present in the ventral root exit and dorsal root entry zone of the spinal cord or even absent. Also, EAE is monophasic, whereas MScl has a random relapsing-remitting or chronic progressive pattern.¹¹ EAE has led to development of the hypothesized immunological basis of MScl pathology.¹² Moreover, the EAE has been instrumental in discovering and developing three of the six currently approved therapies for MScl that diminish its symptoms: Copaxone, Mitoxantrone, and Natalizumab.¹³,¹⁴ For instance, Mitoxantrone, a known cancer drug, was tested in EAE and found to have positive effects, which led to its use in relapsing-remitting MScl, slowing its progression into secondary progressive MScl.¹⁵

Unambiguous current clinical diagnosis of MScl remains diﬃcult, particularly in its early stage, due to the complexity of its pathology and the similarities of these pathologies to that of other neurological diseases/infections. Diagnosis in an early stage is important as early intervention appears beneﬁcial to slow down the long-term progression of the disease.¹⁶ A molecular
biomarker derived for neuroinflammation in the animal model EAE may form a first step toward such an early diagnosis.

The main objective of this study is to find in the cerebrospinal fluid (CSF) of EAE induced Lewis rats metabolic markers of neuroinflammation and to differentiate neuroinflammation from peripheral inflammation. For this a controlled animal study was setup, with a healthy control group, a group injected with inflammatory “booster” (Complete Freund Adjuvant emulsion, CFA) to induce peripheral inflammation and a group injected with CFA and in addition MBP to induce neuroinflammation. Disease progression was monitored, and CSF samples were collected at two different time points. To analyze the metabolic profile of the CSF, we used an untargeted and unbiased biomarker discovery approach in which high-field 1D 1H NMR is combined with pattern recognition methods. To our knowledge, this is the first study applying 1H NMR to analyze rat CSF in the EAE model. A fact that very few rat CSF metabolite studies have been done by NMR is likely due to the limited amount of CSF in rodents. This is not a standard procedure to use such little sample volume in NMR. High quality data could be obtained using only 10 μL of CSF, thanks to the use of advanced NMR including high-field and cryo-probe technology.

We found that the CSF metabolic profile for neuroinflammation is distinct from that of healthy and peripheral inflammation. The metabolites, identified as specific for neuroinflammation, were investigated in a second independent set of animals for the prediction of the early stage of neuroinflammation. The validation of the findings with an external experiment is often acclaimed but rarely practiced in a single study. These diseasespecific markers, detected in the animal model, may lead to a better understanding of the metabolism underlying neuroinflammation and help to develop a molecular diagnosis for the early stage of MScl in humans.

**MATERIALS AND METHODS**

**Experimental Design of EAE Models**

The EAE is one of the most intensively examined and best characterized animal models of autoimmune disease. EAE shares similarities with MScl. Although the EAE model does not mimic all aspects of MScl, this rodent disease model is an excellent experimental system for understanding aspects of the MScl disease.

The first set of male Lewis rats (Harlan Laboratories B.V., The Netherlands) was inoculated on Day 0 as previously described.17

<sup>a</sup> n indicates number of rats (samples) for each group. <sup>b</sup> One sample was discarded due to blood contamination. <sup>c</sup> Three samples were discarded due to blood contamination.

Briefly, a 100 μL saline based emulsion containing 50 μL of Complete Freund Adjuvant H37 RA (CFA, Difco Laboratories, Detroit, MI), 500 μL of Mycobacterium tuberculosis type H37RA (Difco), and 20 μg guinea pig myelin basic protein (MBP) was injected subcutaneously in the pad of the left hind paw of isoflurane anaesthetized animals. CFA was injected for boosting of the immune system, while MBP was injected for induction of neuroinflammation. Next to these MBP challenged rats, referred to as the EAE group (or neuroinflamed group), two control groups were included: a group of animals receiving the same emulsion without MBP (CFA group = peripheral inflammation) and a healthy group undergoing anesthesia only (healthy control). Each group consisted of 30 animals. In each group, half of the animals was sacrificed to collect CSF on Day 10 (Day of onset in EAE group) and the other half on Day 14 (peak of disease in EAE group). The typical progression of disease is summarized in Table 1.

Animals were kept under normal housing conditions with water and food and libitum, weighing between 175 and 225 g at the start of the experiment. Animals were group housed per 3 and cages were randomized across treatments and disease duration.

A second set of male Lewis rats was used to perform another EAE experiment, one year after the first EAE experiment (Table 1), 4 were contaminated with blood therefore they were discarded from the measurements. A set of 86 CSF samples were prepared and measured as described below.

10 μL of rat CSF were thawed at room temperature and 240 μL D<sub>2</sub>O (99.96 at.%D) were added to the bioloid in order to obtain sufficient amount of sample for the NMR measurement. TSP-d<sub>4</sub> (Sodium 3-(trimethylsilyl)propionate-2,2,3,3-d<sub>4</sub>) (99 at.%D) was used as internal standard for chemical shift reference (δ 0.00 ppm). For the latter, 25 μL of 8.8 mM TSP-d<sub>4</sub> stock solution in D<sub>2</sub>O was added to 250 μL of rat CSF to a final concentration of 0.8 mM TSP. The TSP-d<sub>4</sub> stock was prepared by weighing in dry TSP-d<sub>4</sub>. The pH of the CSF was adjusted to around 7 (7.0–7.1) by adding phosphate buffer (9.7 μL 1M, to a final concentration of 35 mM). The final CSF NMR sample (284.7 μL) was then transferred to a SHIGEMI microcell tube for measurements.

The 1D 1H NMR spectra of rat CSF samples were acquired on an 800 MHz Inova (Varian) system equipped with a 5 mm triple-resonance, Z-gradient HCN cold-probe. Suppression of water was achieved by using WATERGATE (delay: 85 μs).<sup>18</sup> For each 1D 1H NMR spectrum, 512 scans were accumulated with a spectral width of 9000 Hz resulting in a total of 18K points. The acquisition time for each scan was 2s. Between scans, a 8s relaxation delay was employed. Prior to spectral analysis, all acquired Free Induction Decays (FIDs) were zero-filled to 32K data points, multiplied with a 0.3 Hz line broadening function, Fourier transformed, manually phased and the TSP internal reference peak was set to 0 ppm by using ACD/SpecManager software version 11.0.<sup>19</sup> All 86 rat CSF spectra were acquired and preprocessed as described above. However, due to high line broadening of the internal standard (TSP), four spectra were not included in spectral analysis. In total, 82 spectra were subsequently transferred to Matlab, version 7.6 (R2008b) (Mathworks, Natick, MA), for further analysis.

The preparation and data acquisition of CSF samples from the second EAE experiment are described in the Supporting Information.

Preprocessing of NMR Spectra. The NMR spectral data were preprocessed, which typically involves baseline correction, alignment, binning, normalization and scaling. Baseline correction of NMR spectra was performed by applying Asymmetric Least Squares method.<sup>20</sup> Fluctuation in experimental conditions like sample temperature, pH, ionic strength can lead to chemical shift variations, therefore NMR spectra were aligned by using improved parametric time warping (I-PTW).<sup>21</sup> A further problem is the high dimensionality of the data (ca. 10 000 variables). It is common to apply binning to this kind of data, which reduces the number of variables. To perform proper spectral bucketing we used adaptive intelligent binning.<sup>22</sup> The chemical shift range δ 0.75–4.15 was used for the binning procedure because it contained relevant information. Next, spectral resonances corresponding to one...
metabolite were summed and regrouped in one bin. This procedure was applied to the resonances where no overlapping was present and it led to 153 bins in total. To make spectra comparable between different samples, the final step of preprocessing consisted of integral normalization and supervised vast scaling applied to the binned data.23

**Metabolites Identification and Quantification.** Metabolite identification was carried out by using the 800 MHz library of metabolite NMR spectra from the Chenomx NMR Suite 5.1 (pH 6–8). The library of metabolite spectra is obtained based on a database of pure compound spectra acquired using a particular pulse sequence and acquisition parameters, the tn-noesy-pre-saturation pulse sequence with 4s acquisition time and 1s of recycle delay.24 The Chenomx NMR Suite software fits the spectral signatures (singlets, doublets, triplets etc.), that is, the peak shapes, of a compound from an internal database of reference spectra to the experimental NMR spectrum.

For quantification, that is determination of the concentrations of individual metabolites, Chenomx NMR Suite 5.1 uses the concentration of the known reference signal as calibration (in this case TSP-d4). Note that the Chenomx approach is that peak shapes are fitted to the experimental ones. In contrast, peak integration, which is often employed for quantification, is very sensitive to baseline distortions and even slightly overlapping resonances cannot reliably be integrated. Peak-shape fitting, like employed in Chenomx, is instead not much affected by baseline distortions. Moreover, even when some of the resonances and/or part of a resonance signature (triplet etc.) of a compound overlap with that of another compound, the peak shape can still be fitted with reasonable accuracy and the concentration of the compound reliably determined.

**Data Analysis Strategy.** Explorative analysis, by means of Principal Component Analysis (PCA),25 was used first to extract and display the systematic variation in the data.

The strategy for multivariate supervised analysis, using Discriminant Analysis by Projection on Latent Structures (PLS-DA)26 was designed in accordance with the experimental design summarized in Table 1. The data contain three main groups (healthy control “C10” and “C14”, peripheral inflammation “P10” and “P14” and mixture of neuroinflammation and peripheral inflammation “N10” and “N14”) in two time points (Day 10 and Day 14). The two time points (Day 10 and Day 14) were analyzed separately, and we always differentiated between two groups. We have used PLS-DA, since it gives more interpretable results and it enabled us to observe the influence of single effects (i.e., peripheral inflammation, neuroinflammation or disease-progression) on the CSF metabolic profile.

To corroborate the results we used another supervised method, ANalysis Of VAriance-Principal Component Analysis (ANOVA-PCA). The analysis was performed on each time point separately as well as on the two time points combined. Variables (metabolites) differentially profiled across groups of interest were selected based on regression coefficients in PLS-DA and on ANOVA-PCA, Hotelling T² statistic with p-value inferior than 0.05.27

**Model Construction and Validation.** PLS-DA is a variation of PLS.28 PLS-DA uses the group information to maximize the separation between groups of observations. It is currently widely used in metabolomics because of its ability to cope with high correlations between variables. In PLS-DA a linear model is constructed according to eq 1:

$$y = Xb + r$$  \(\text{(1)}\)

where, \(X\) is a data set matrix, \(y\) is a vector of group memberships, \(b\) is a vector of regression coefficient, and \(r\) is a vector of model residuals. The regression coefficients reflect the relative importance of the variables in the PLS-DA model. We divided the data into a training and a test set using the Duplex algorithm29 in such a way that the number of samples in the training set was equal for every considered group. The amount of samples in the test set was equal to at least 25% of the total number of samples but not more than 30%. To prevent model overfitting we applied the cross model validation (CMV) procedure, introduced by Andersen et al. and Gidskehaug et al.,30,31 in which double cross validation procedures are included for model optimization, the variable selection based on jack-knifing and final model performance assessment. All MATLAB routines for performing variable selection can be found in this reference.31

Finally, all PLS-DA models were validated with the independent test set. For every considered model the specificity and sensitivity of the test set were calculated. The final PLS-DA model was applied to the whole data set if the accuracy of the independent test set was satisfactory (i.e., above 90% of correct classification).

In order to predict the class labels (\(Y\)) of validation set the scaled spectra (\(X_{\text{new}}\)) have to be multiplied by regression coefficient (\(b\)) obtained from PLS-DA model (i.e., \(Y = X_{\text{new}}b\)). Please keep in mind that scaling performed on validation set applied all necessary parameters (i.e., mean and standard deviation) from training set.

**ANOVA-PCA.** Previously we showed that this approach allows identifying the relevant variables to distinguish groups.27 In this study the main factors are the metabolites effect (\(M\)) and the treatments effect (\(T\) (groups)) plus a random dimension linked to the individual variations. The ANOVA model is given in eq 2:

$$X_{ijk} = \mu + M_i + T_j + MT_{ij} + e_{ijk}$$  \(\text{(2)}\)

where \(\mu\) is a general mean, \(e\) is the error term and \(MT_{ij}\) indicates the interactions between main effects. The interaction between metabolites and treatments, that is, groups (\(MT_{ij}\)), is of highest interest because it reflects the influence of the different treatments on the intensity of metabolites when all others effects are averaged out. Therefore PCA is performed on the matrix of interaction effects to identify metabolites that contribute to this interaction. If the treatment (\(j\)) is relevant for the metabolite (\(i\)), the interaction \(MT_{ij}\) is significantly different from zero.

**Heat Map and Correlation Network Map.** To represent the relevant metabolites concentrations in groups “C14”, “P10” and “N14” we generated a heat map from NMR metabolomics data. The heat map is a graphical representation of NMR data in two-dimensional map, where the metabolites concentrations are illustrated as colors. Every concentration value was standardized according to the reference group (healthy group “C14”), i.e. by subtracting mean and dividing by the standard deviation of healthy controls. In that way the metabolites concentrations are expressed in values of standard deviation from the control group.

The concentration of a certain metabolite does not fluctuate independently, but may be correlated and change with the others metabolites. To examine the level of observed changes among metabolites we calculated the Spearman’s correlation between relative metabolites concentrations in groups “C14” and “N14”, as well as in groups “P10” and “N14”. Spearman correlation
calculates the correlation of the ranks for metabolites concentrations, given in eq 3.

\[
C_r = 1 - \frac{6 \sum_{i=1}^{n} d_i^2}{n(n^2 - 1)}
\]  

(3)

where, \(C_r\) is a Spearman’s correlation, \(d_i\) is a difference between ranks of each sample on the two metabolites, and \(n\) is the number of samples.

Extreme variations in concentration values have less influence on the Spearman correlation than on the Pearson's correlation. The calculated correlations are then transferred to Graphviz 1.01 for network map visualization (http://www.graphviz.org). In the network map two metabolites are connected with a link if their correlation coefficient is relevant, that is, exceeds a given threshold. The correlation between metabolites concentrations was significant if its value was superior than 0.7 and p-value was inferior than 0.05.

## RESULTS

### Overview of the Available Data

Eighty-six NMR spectra were measured, while 82 spectra were included in further analysis. An example of a \(^1\)H NMR spectrum of rat CSF is shown in Figure 1c in the chemical shift region between 0.8 and 2.7 ppm. This region contains several signals from carboxylic acids and amino acids protons. Some of the metabolites are named in Figure 1c. For the analysis, the NMR spectra were divided into 153 bins, which contain resonances of 33 identified metabolites and some unidentified signals. The identified metabolites are listed in the Supporting Information. The information concerning the second EAE model can be found in the Supporting Information.

The average neurological scores and standard deviations for group “N14” are shown in Figure 1b, the information of each individual animal is listed in the Supporting Information. As can be observed, the animals showed motor dysfunction at day 11. The average day of onset was 11.56 (±0.2). This means that on average, animals were disabled for a period of 2.4 days (±0.2) at the sampling day. In group “N14” only one animal showed disease duration shorter than 2 days (onset on day 13). The maximum score reached was on average 4.5 (±0.2). Six animals showed a maximum score above this average. The average peak day (as defined by the first day of maximum score per individual animal) was 13.3 (±0.2). An idea would be to use the neurological scores for regression purpose for groups “N10” and “N14”.

However all animals in group “N10” had neurological scores equal zero, while animals in group “N14” quite spread values from 0 until 6. This would cause an artificial compactness of samples from group “N10”, while group “N14” very spread. This would lead to biased PLS results. Therefore, the neurological scores were not used.

### Explorative Analysis by PCA

Before performing pattern recognition, the spectra of 82 rat CSF samples were checked for outliers. In total 3 spectra were detected as outliers and were removed from the final analysis. Figure 1d shows the PCA score plot of the total data set (79 vast scaled spectra). This plot shows that the samples belonging to group “N14” are clearly separated from the others samples along PC2. It also reveals that a large source of variance in the data does not correspond to the available groups. No clear grouping is present since most of the groups overlap. With PCA only, we are not able to distinguish all analyzed groups. Therefore, we needed to use more dedicated methods.

### Supervised Multivariate Analysis by PLS-DA and ANOVA-PCA

**PLS-DA of \(^1\)H NMR CSF Data.** PLS-DA models of the \(^1\)H NMR spectra were performed to extract information on the metabolic effects of the different group treatments as presented in Table 1. In Table 2 in the Supporting Information, the specificity, sensitivity, the correct classification rate for the test set and the total number of variables in the PLS-DA models are presented. Metabolites that contributed significantly to the group separation are listed in Table 3 in the Supporting Information. The results of these PLS-DA models urged us to revise the assumed effects for some groups of Table 1. The summary of the particular effects investigated by the different PLS-DA models is presented in Table 4 in the Supporting Information. As the first part of supervised analysis the comparison between “C10” and “C14” has been performed in order to find the metabolites that represent metabolic evolution over days. Later, this information was used to check if any of the discriminating metabolites are related to metabolic variation over time. Following, a detailed analysis of the results of the different models is given.

The score plots of final PLS-DA models are presented in Figures 2a–e. Note that score plots are used only for illustration purpose and do not determine the classification of PLS-DA model.

**Effect of Neuroinflammation and Peripheral Inflammation.** The PLS-DA model for groups “C10” versus “N10” allows one to study the combined effect of neuroinflammation and peripheral inflammation. This model has a high prediction ability of 100% for the independent test set. The area under the curve (93.4%) indicates that group “C10” and group “N10” are well separated and the PLS-DA has a high model performance. The CSF metabolic profile of the EAE-affected group can thus without a doubt be differentiated from the metabolic profile of the healthy group.

**Effect of Neuroinflammation.** The PLS-DA model for groups “P10” versus “N10” allows one to discriminate the effects of peripheral inflammation and neuroinflammation on the CSF metabolic profile. This model shows poor prediction (accuracy for the independent test set is 62.5%), and the sensitivity for group “N10” is very low (predicted as belonging to group “P10”). The score plot (Figure 2b) illustrates two subgroups in group “N10”, one overlapping with group “P10” and a second cluster further away. This result suggests that animals in group “N10” are heterogeneous regarding to the disease response. Probably, within group “N10” some animals did not show any neuroinflammation yet; indeed at Day 10, no neurological deficits have been observed in this particular experiment. Therefore, for some animals the peripheral inflammation is still the dominant effect since the neuroinflammation has not developed yet. A hierarchical clustering was performed on group “N10” to confirm the heterogeneity of the group (data not shown). Three samples were identified as outliers for group “N10”. This suggests that the response of the animals to the disease in the EAE model was not uniform and some animals’ response is shifted along time. The neurological scores recorded for group “N10” on average were equal to 0. This means that by examination of the rat’s motor system no external neurological or pathological physical signs were observed. The heterogeneity of group “N14” was further investigated with ROC curve analysis. The area under curve (60%) shows that group “P10” and group “N10” are not well separated.
The PLS-DA model for groups “N10” versus “N14” allows one to study the progression of disease. The classification model has perfect accuracy (overall classification of 100% for independent test set).

Investigation of the second time point (Day 14) by PLS-DA allows one to identify the metabolites differently profiled during the peak of disease. The PLS-DA model of “C14” versus “N14” has perfect prediction ability (overall classification is 100% for independent test set).

Effect of Peripheral Inflammation during the Peak of the Disease. The overall correct classification rate for independent test set of this model is only 65%. The area under the ROC curve.
is 59%. These results suggest that the metabolic profiles of group “C14” and group “P14” are quite similar. On the basis of these data, we can make the statement that at Day 14 the effect of an immunopotentiator, that is, CFA, was not measurable based on the metabolite profile. Our interpretation of these results is that peripheral inflammation has vanished by Day 14 and group “P14” is actually healthy. This interpretation is coherent with the absence of external symptoms (i.e., fever and swelling pad).

Since group “P14” is not inflamed anymore, the PLS-DA models of group “P14” vs “N14” and “N14” vs (“C14”&“P14”) give similar results as the PLS-DA model of the healthy group “C14” vs group “N14”. In both situations, the overall correct classification for independent test set is 100%. The PLS-DA model of “P10” vs “P14” is described in the Supporting Information.

**PLS-DA model should carry the information about the metabolites differentially profiled in peripherally inflamed and neuroinflamed subjects. The PLS-DA model shows perfect prediction ability with an overall correct classification of 100% for independent test set. On the basis of our results, these two groups indeed have different metabolic profiles.**

**ANOVA-PCA of 1H NMR CSF Data.** To confirm the results from the PLS-DA models, we used ANOVA-PCA as a corroborative technique to identify metabolites that vary significantly between groups. The factors modeled in this study are the factor treatment (CFA, CFA+MBP or no treatment) and the different metabolites (the Metabolite factor). The resulting biplots of the ANOVA-PCA are displayed in Figure 2a–d, while the group specific metabolites are summarized in Table 5 in the Supporting Information. In the next section, an overview of the results derived from ANOVA-PCA is discussed.

Except for a few metabolites, the same set of metabolites for peripheral as well as neuroinflammation was selected by ANOVA-PCA. ANOVA-PCA showed that the metabolic profiles of healthy group, peripheral inflamed and neuroinflamed animals can be distinguished. Moreover it showed that groups “C14” and “P14” have similar metabolic profiles.

The most discriminating metabolites and their absolute concentrations are presented in Table 2; their short biological significance was standardized with respect to the healthy controls. On the contrary, alanine is reduced. The intraindividual variations between groups. The factors modeled in this study are the factor treatment (CFA, CFA+MBP or no treatment) and the different metabolites (the Metabolite factor). The resulting biplots of the ANOVA-PCA are displayed in Figure 2a–d, while the group specific metabolites are summarized in Table 5 in the Supporting Information. In the next section, an overview of the results derived from ANOVA-PCA is discussed.

As a final step, to make the PLS-DA model more robust and generic (i.e., machine independent), PLS-DA model was constructed for the absolute concentration of the metabolites. This is, however, a time-consuming step, and therefore, we performed it only for the “P10” and “N14” groups. The PLS-DA model for group “P10” versus group “N14” shows perfect prediction ability with an accuracy of 100% on the independent test set. The score plot of this model is shown in the Supporting Information (Figure 3). This model is further validated with an independent set of animals, derived from a second EAE experiment.

**Heat Map and Correlation Network Map**

To represent the individual differences in metabolite concentrations of healthy controls (“C14”), peripherally inflamed (“P10”) and neuroinflamed (“N14”) animals, a heat map of the metabolomics data was constructed (Figure 3a). The metabolite concentrations were standardized with respect to the healthy group “C14”. The metabolites included in the heat map correspond to the significant ones shown in Table 2. The heat map shows that the metabolite concentrations, characteristic for neuroinflammation, change significantly in group “N14”. For instance, arginine concentration is elevated in group “N14” in comparison to healthy and peripherally inflamed controls. On the contrary, alanine is reduced. The intraindividual variations are still observable.

3-Hydroxy stands for 3-hydroxyisovalerate; NAA stands for N-acetylaspartate.
To assess the correlation between metabolites, we calculated Spearman’s correlation between relative metabolite concentrations in groups “C14” and “N14”, as well as in groups “P10” and “N14”. Those correlations are visualized as a network map (Figure 3b-c) to provide an overview of similarities between different metabolites in the considered groups. In Figure 3b, a correlation network map between metabolites in healthy group “C14” and neuroinflamed group “N14” is presented. There are just a few shared correlations (indicated with a dashed line), that is, significant correlations seen in both groups. These correlations are thus not influenced by neuroinflammation. Figure 3c shows the correlation network map between metabolites in peripherally inflamed group “P10” and neuroinflamed group “N14”. There are only a few correlations present in group “P10” (solid, black line), and shared correlations between groups “P10” and “N14” are absent. What is particularly noteworthy is the fact that many correlations, present in the healthy control, vanished due to neuroinflammation, but also some new correlations appeared.

**Prediction of Neuroinflammation in an Independent Set of Animals**

To confirm the validity of the discovered disease specific markers for neuroinflammation, we used an independent set of samples coming from another EAE experiment, in which we want to predict neuroinflammation in an early stage. The absolute concentration of our markers was determined for the group with peripheral inflammation at Day 10 (here called group “P10–2”) and the group with peripheral and early neuroinflammation at Day 10 (here called group “N10–2”). All peripherally inflamed animals (group “P10–2”) are correctly classified. Animals with peripheral inflammation and early neuroinflammation (group “N10–2”) are also correctly classified, except for one animal. The overall correct classification for the independent set of samples is 95.8%, with specificity for group “P10–2” and group “N10–2” equal to 100% and 91%, respectively. The projection of these independent samples on the PLS-DA score plot derived from group “P10” versus “N10” is shown in Figure 2f. It is important to note that the misclassified sample is located close to the borderline between the two groups. This result suggests that proposed markers have a similar behavior in the second study.

**DISCUSSION AND CONCLUSION**

Supervised analysis of CSF ¹H NMR data revealed significant changes in biochemical composition of the CSF metabolic profile among the analyzed groups. PLS-DA and ANOVA-PCA have been used to model the metabolic profiles from rat CSF. The small differences between PLS-DA and ANOVA-PCA results
may arise from the principles of the two methods. PLS-DA aims to select a subset of metabolites that gives the highest separations between groups. This may imply that not all discriminatory metabolites are selected. In the case of ANOVA-PCA, the amount of selected variables mostly depend on α level Hotelling $T^2$. In addition, the two different scaling approaches applied before PLS-DA and ANOVA-PCA may have an influence on the selection of metabolites.

Interpretation of PLS-DA models and ANOVA-PCA yielded a set of relevant metabolites, which are shown in Table 2. In this section we further discuss their biological interpretation.

**Metabolites Related to Neuroinflammation: Choline, N-Acetylaspargtate, Creatine, Lysine, Arginine, Alanine and Malonate**

The concentration of choline was elevated in groups “N10” and “N14”. However, the choline concentration stayed invariant between two control groups “C10” and “P10”. In a previous study, where MScI patients and EAE model in marmoset were studied by $^1$H NMR spectroscopy, higher choline concentrations have been reported as a marker for demyelination in urine. This metabolite is required for synthesis of neurotransmitter acetylcholine, and phosphatidylcholine. The increase in choline concentration could be due to demyelination and/or cell membrane breakdown.

Another metabolite found as being highly correlated with EAE-affected groups “N10” and “N14” and that enabled us to differentiate these groups from the others was N-acetylaspargtate (NAA). This compound is known as a marker of neuronal damage. Its concentration was elevated in the “N14” group. In addition, this metabolite distinguished neuroinflammation from peripheral inflammation in the PLS-DA model. NAA is a free amino acid present in neuronal cell, and it has been culpably involved in many processes of the nervous system, for instance, it may be involved in the myelin production, regulation of neuronal protein synthesis, or the metabolism of several neurotransmitters such as aspartate or N-acetyl-aspartyl-glutamate.

Two other metabolites, creatine and malonate, were found to vary between the two EAE-affected groups. Creatine level was found to be up-regulated in group “N14”. Creatine is considered as one of the principal brain metabolite. Its changes in concentration are seen in many other neuro-degenerative disorders and are caused by glosis or scarring of neuron (demyelination). An elevated level of creatine in patients with MScI was found in a previous study and has been associated as marker of glosis. Up-regulated creatine level could be due to a change in the cellular composition, either increased inflammatory cells or glial cells. The malonate level was reduced in neuroinflamed group “N14”. Another metabolite found to be reduced in neuroinflamed group “N14” is alanine. Reduced level of alanine in patients with MScI in comparison to patients with cerebrovascular disease was found in a previous study, where Sinclair et al. used NMR spectroscopy to evaluate the ability of metabolomics analysis to differentiate neurological disease. Alanine is used as a source for pyruvate for energy metabolism or to synthesis of macromolecules within neural and immune cells. Reduction of alanine concentration may be connected to energy metabolism, since it might be used by invading cells.

Lysine and arginine were found to have a high correlation with EAE-affected groups “N10” and “N14”. Lysine and arginine levels were up-regulated in group “N14” compared to “N10” and in “N10” compared to “P10”. This indicates their relation to neuroinflammation. Lysine and arginine are metabolites that may differentiate peripheral inflammation from neuroinflammation. Arginine is used to synthesize nitric oxide (NO). Elevated levels of NO oxidation products in the CNS have been shown in bacterial meningitis in cerebral lupus erythematosus. Recently it was demonstrated that increased levels of NO oxidation plays a part in the generation of MScI symptoms. Inhibition of NO synthesis may suppress or emphasis EAE. However, the precise role of NO in EAE and MScI still remains elusive and unclear. Qureshi and coworkers have studied a role of neurotransmitters amino asids in CSF of MScI patients. They have reported increased level of lysine in CSF in MScI patients.

**Metabolites Related to Peripheral Inflammation: Citrate, Glutamine, Lactate and 3-Hydroxyisovalerate**

Citrate is a key metabolite to differentiate the healthy group “C10” from the peripherally inflamed group “P10” but also the peripherally inflamed group from the EAE affected group “N14”. Reduced citrate is in line with a previous study of Sinclair and coworkers. The difference in citrate level is larger between the peripherally inflamed and neuroinflamed group than between the healthy control and the peripherally inflamed group. The citrate level may indicate the degree of inflammation. Citrate is released to a larger extent from astrocytes than from neurons. This metabolite is an intermediate in tricarboxylic acid cycle (TCA). In the study of Smith and co-workers, the metabolic activity of proteins from myelin and nonmyelin fractions of spinal cords of Lewis rats with EAE was investigated using $^{1,14}$C]leucine as a protein precursor. In this study, they showed that the decreased activity of the TCA cycle exists. However, the implication of the citrate alteration is unclear although it was already noted in Alzheimer’s and in MScl disease.

Glutamine is an amino acid, which plays an important role in brain metabolism. This metabolite is involved in energy metabolism. It was shown that glutamine is a necessary nutrient for cell proliferation, serving as a specific fuel for inflammatory cells and enterocytes and, when present in appropriate concentrations, enhancing cell function. During inflammatory states, glutamine consumption may outstrip endogenous production and a relative glutamine deficiency state may exist.

A higher level of lactate was found in group “N10” in comparison to group “N14”. Predominant lactate peaks have already been reported in inflammatory CNS diseases. The amount of CSF lactate depends largely on production from CNS glycolysis. Increased lactate production by immune cells is observable in the presence of inflammation. Although elevations in CSF lactate may occur because of many different processes, for instance, hypoxia of inflamed tissues, reduced blood flow from cerebral edema, and granulocyte and bacterial metabolism. In addition, elevated lactate levels have been identified in vitro.

The reduced level of 3-hydroxyisovalerate was established for group “N10” and group “P10” when compared with the healthy group. This suggests that this metabolite is involved in peripheral inflammation. However, this result deserves more attention since a previous publication demonstrated an increase in 3-hydroxyisovalerate level in some MScI patients.

**Conclusion**

We investigated the effect of neuroinflammation and peripheral inflammation on the metabolic state of CSF in the rat EAE model, a mimic of the neuroinflammatory aspect of the early stage of MScI. In the animal study untargeted and unbiased biomarker discovery approach consisting of high-field 1H NMR combined with multivariate data analysis was employed.
CSF is demonstrated as a valuable biofluid for the investigation of neurological disorders in the CNS. We found that \(^1\)H NMR is a powerful technique capable of providing information for the identification and quantification of a large number of metabolites in CSF.

The use of two statistical techniques (PLS-DA and ANOVA-PCA) contributes significantly to the reliability of the results. The two methods are corroborative, because the overall results obtained by PLS-DA and ANOVA-PCA were found to be coherent.

The CSF metabolic profile for neuroinflammation is distinct from that of healthy and peripheral inflammation and characterized by changes in concentrations of metabolites such as creatine, arginine, and lysine. Peripheral inflammation was only seen at Day 10 and absent at Day 14. A further interesting observation was that the correlation network map is much more complex for the healthy group than for the groups affected by peripheral inflammation or neuroinflammation. Disappearance of correlation between metabolites in peripherally inflamed and neuroinflamed animals might be related to change of penetrability of the blood–brain barrier (BBB). Under standard physiological circumstances, BBB controls the homeostasis of the interstitial cerebral fluid. It is known that during EAE changes in the BBB function occur. It causes disruption in the BBB and effects the saturable transport system of substances involved in disease process. Injection of CFA can itself lead to increased BBB permeability to small molecules and even certain serum proteins. These disturbances might then cause changes in metabolites flux across BBB and relations between them. For instance, the correlation might become more nonlinear or weaker and therefore be absent in the disease stage under a selected threshold. In addition, in EAE there is a strong increase in infiltration of the BBB by monocytes and activated lymphocytes that is bound to change the metabolite profile of the fluids. Not only a disrupted BBB leads to “leakage” but activated immune cells crossing the BBB and entering the interstitial fluid and the CSF produce metabolites that change the overall profile of the fluids they are in.

Interestingly, some markers of neuroinflammation have been connected to demyelination and neuronal damage. In EAE model induced with MBP demyelination is missing or limited to the ventral root exit and dorsal root entry zone of the spinal cord. In the case of Lewis rats primary demyelination is restricted to occasional perivenous myelin sheaths. In general, demyelination is more distinct when addition of other CNS antigens to the MBP results in pronounced demyelination. In addition, some demyelination was observed in guinea pig EAE model incorporated with MBP inoculums utilized for sensitization. However, the presence of demyelination in the EAE model induced with MBP is a matter of debate. Therefore, we believe that it needs additional investigations. In the current study, the presence of demyelination could be investigated by, for instance, repeating the EAE model and then performing histology studies or electron microscopy of spinal cord. Another possibility would be to use Magnetic magnetic resonance imaging to study the pathology of rats’ brain and spinal cord. These steps could demonstrate the presence or absence of demyelination.

By using an independent set of animals, that is, coming from another EAE experiment, we demonstrated that this model and ipso facto the disease specific markers have ability to predict neuroinflammation in its early stage with high accuracy. Thus, these animal-model-based markers may be used to diagnose the early stage of neuroinflammation. Further developments will include the investigation and translation of our results to a clinical context, that is, how these results can be used to predict MS.
