Soliton density in Rb$_2$ZnBr$_4$

R. Blinc, V. Rutar, B. Topič, F. Milia,* and Th. Rasing

J. Stefan Institute, E. Kardelj University of Ljubljana, Ljubljana, Yugoslavia

(Received 28 May 1985)

The modulation wave in Rb$_2$ZnBr$_4$ is pinned over most of the incommensurate phase and $^3$Rb NMR line-shape analysis cannot distinguish between a true incommensurate phase and a large-period commensurate phase with $N=17$. The temperature variations of the soliton density, the line shape, and the spin-lattice relaxation rate speak for the coexistence of a large number of domains pinned by impurities rather than for the existence of a devil's staircase and pinning by the discreteness of the crystal lattice. The large thermal hysteresis in the soliton density demonstrates the presence of a metastable, impurity-induced "chaotic" phase with random intersoliton spacing which exists even far below the incommensurate-commensurate transition.

I. INTRODUCTION

Rb$_2$ZnBr$_4$ represents one of the first known examples of one dimensionally modulated incommensurate insulators.$^{1-10}$ The nature of the incommensurate phase in Rb$_2$ZnBr$_4$ between $T_1=346$ K and $T_c=187$ K, however, is still far from being well understood. In contrast to isostructural Rb$_2$ZnCl$_4$ and K$_2$ZnCl$_4$ and in contrast to the predictions of the Landau theory,$^{1,4}$ the modulation wave vector does not change with temperature over more than 140 K. It has been recently found$^{5,6}$ that in the high-temperature part of the incommensurate phase the modulation wave vector equals $q_0$, so the unit cell should be in fact commensurate and 17 times larger than in the high-temperature phase above $T_1$. This result is rather unusual since commensurate phases with a large superstructure should exist over a narrower range of temperatures than phases with a small superstructure. Another surprising result is that close to the incommensurate-commensurate transition successive jumps in the modulation wave vector were observed, but the various "steps" are not specified by an exact fraction as predicted in the devil's-staircase model$^7$ and, moreover, seem to coexist in a certain temperature range.$^{5,6}$

Experimentally, it is rather hard to distinguish higher-order commensurate phases with large periods from true incommensurate phases.$^{8,9}$ Here we wish to investigate $^{89}$Rb $\frac{1}{2}$ $\rightarrow$ $\frac{1}{2}$ quadrupole perturbed nuclear magnetic resonance can say about the nature of the incommensurate phase in Rb$_2$ZnBr$_4$. We wish as well to redetermine$^{10}$ the soliton density in this system using recently improved line-shape analysis techniques.

II. LANDAU THEORY

A. The soliton density and the Landau theory

For systems of interest like Rb$_2$ZnBr$_4$, (NH$_4$)$_2$BeF$_4$, etc., where the order parameter $Q$ has two components, the Landau free-energy density can be expressed$^{11}$ as

$$g(x) = \frac{\alpha}{2} (Q^*Q) + \frac{\beta}{4} (Q^*Q)^2 - \frac{\gamma}{2} [Q^n + (Q^*)^n - (Q^*Q)^{n/2}]$$

$$- \frac{i \delta}{2} \left[ \frac{Q}{dx} \frac{dQ}{dx} - \frac{Q}{dx} \frac{dQ}{dx} + \frac{\kappa}{2} \frac{dQ}{dx} \right]^2.$$  (1)

Here $Q$ is complex. For convenience we have retained a higher-order term $(Q^*Q)^{n/2}$ considering only even $n$, e.g., $n=10$ for [N(CH$_3$)$_4$]$_2$ZnCl$_4$, $n=6$ for Rb$_2$ZnCl$_4$, $n=4$ for (NH$_4$)$_2$BeF$_4$, and $n=2$ for chiral smectic liquid crystals in an external magnetic field. Here we have $\alpha=\alpha_0(T-T_0)$ and $\beta, \kappa, \gamma, \delta > 0$. Introducing polar coordinates $Q=A \exp(i\varphi)$, Eq. (1) can be rewritten as

$$g(x) = \frac{\alpha}{2} A^2 + \frac{\beta}{4} A^4 + \gamma A^6 \cos^2 \left( \frac{n\varphi}{2} \right)$$

$$- \delta A^2 \varphi' + \frac{\kappa}{2} A^2 (\varphi')^2.$$  (2)

Minimizing

$$F = \frac{1}{x_0} \int_0^{x_0} g(x)dx$$

with respect to $\varphi$ in the constant-amplitude approximation $A=A_0 \neq A(x)$ and making use of the identity

$$\cos^2(n\varphi/2) = \frac{1 + \cos(n\varphi)}{2},$$

one finds the Euler equation for our problem (i.e., the sine-Gordon equation)

$$\frac{\partial g}{\partial \varphi} - \frac{d}{dx} \frac{\partial g}{\partial \varphi'} = 0,$$  (3a)

yielding

$$\kappa \varphi'' = - \frac{n}{2} \gamma A_0^{-2} \sin(n\varphi)$$  (3b)

with $\varphi' = d\varphi/dx$ and $\varphi'' = d^2\varphi/dx^2$.

The first integral of this equation is
where $\eta$ is an integration constant. The maximum value of the derivative of the phase, $q_\text{max}'$, determines the soliton width $d_0$ (Fig. 1), which is given by

$$q_\text{max}' = \frac{2\pi}{d_0 n} = \left(\frac{2\eta}{\kappa}\right)^{1/2}. \quad (5)$$

The intersoliton distance is, on the other hand, obtained as

$$x_0 = \left(\frac{\kappa}{2\gamma A_0^{-2}}\right)^{1/2} \frac{4}{\kappa} k K(k), \quad (6)$$

where $K(k)$ is the complete elliptic integral of first kind,

$$K(k) = \int_0^{\pi/2} \frac{d\phi}{(1-k^2\sin^2\phi)^{1/2}}, \quad (8a)$$

and

$$k^2 = \frac{1}{1+\Delta^2} = \frac{\gamma A_0^{-2}}{\eta}. \quad (8b)$$

The relation between $\varphi$ and $x$ as well as between $x_0$ and $d_0$ is illustrated in Fig. 1 both for large and small $\Delta$.

The soliton density which measures the volume fraction of the crystal in the incommensurate domain walls$^{12}$ is now obtained as

$$n_s = \frac{d_0}{x_0} = \frac{\pi/2}{K(k)}. \quad (9)$$

It should be noticed that the soliton density $n_s$ as defined above measures the “domain-wall fraction” and it is not equal to the inverse soliton separation $1/x_0$ which measures the number of solitons per unit length. Since the soliton width $d_0$ only weakly depends on temperature, these two quantities are proportional to each other. On approaching the plane-wave limit the soliton separations are of the same order or smaller than the soliton width; therefore $n_s$ as defined above gives a better description of the true physical situation than $1/x_0$. The parameter $k$ is within the constant-amplitude approximation determined by minimizing

$$F = \frac{1}{x_0} \int_0^{x_0} g(x)dx$$

with respect to $\eta$, yielding

$$E(k) = \frac{\pi \delta}{4} \left(\frac{2}{\kappa \gamma A_0^{-2}}\right)^{1/2}. \quad (10)$$

The temperature $T$ enters the above expression through the amplitude of the order parameter, $A_0^2 = a_0 (T-T_c)/\beta$. Here $E(k)$ is the complete elliptic integral of the second kind,

$$E(k) = \int_0^{\pi/2} (1-k^2\sin^2\phi)^{1/2} d\phi.$$

It should be noticed that for $T \to T_c$ (i.e., $A_0 \to 0$), $k \to 0$, $\Delta^2 \to \infty$, and $K(k) \to \pi/2$, so that $n_s \to 1$. For $T \to T_1$ one finds, on the other hand, $\Delta^2 \to 0$, $k^2 \to 1$, $K(k) \to \infty$, and $n_s \to 0$. It should be also pointed out that the soliton density $n_s$ and the density of the commensurate domains, $n_c$, are related by $n_s + n_c = 1$. The temperature dependences of $n_s$ and $n_c$, as predicted by the Landau theory, are illustrated in Figs. 2 and 3. The constant-amplitude approximation $A = A_0 = A(x)$ breaks down$^{13}$ very close to $T_c$.

It should be stressed that the temperature dependences of the soliton density $n_s$ and the incommensurate wave vector $q = 2\pi/x_0$ are qualitatively different both in the constant-amplitude approximation, $A = A_0$, and in the more realistic case with $A = A(x)$. The difference is due to the temperature dependence of the soliton width $d_0$. Near $T_1$, $d_0$ decreases with decreasing temperature faster than $x_0$, resulting in a rather smooth drop of $n_s$ though $q = 2\pi/x_0$ is nearly constant. Close to $T_c$, $x_0$ is critical and $n_s$ and $q$ vanish in the same way.

If the continuum approximation is dropped and the discreteness of the crystal structure is taken into account, a chaotic phase intermediate between the incommensurate and commensurate phases should occur.$^{14}$ The same is true if defects are taken into account.$^{15}$ Quenched random impurities destroy$^{15}$ the long-range order in the incommensurate phase below $d = 4$ dimensions and lead to the formation of domains. Hence $T_1$ and $T_c$ mark no phase transitions in the strict sense if quenched disorder is taken into account.

**B. The NMR line shape**

The real displacement $u$ of the $i$th nucleus in an incommensurate phase is an admixture of a symmetric and an

 FIG. 1. Spatial variation of the phase $\varphi$ of the modulation wave for different soliton densities $n_s = d_0/x_0$. Here $d_0$ is the soliton width and $x_0$ the intersoliton spacing. The spatial variable $x$ is measured in units of $x_0$. 
SOLITON DENSITY IN Rb\textsubscript{2}ZnBr\textsubscript{4}

The expansion of the NMR frequency in powers of the nuclear displacements is no longer of the special local form \( v_1 = v(u_1(x)) \), but contains\textsuperscript{16} both sine and cosine terms.

The same situation arises if the relation between the frequency and the nuclear displacements is nonlocal:\textsuperscript{16}

\[ v_1 = v(u_1(x_i), u_j(x_j), \ldots) . \]  \hspace{1cm} (13)

In both cases one finds\textsuperscript{16}

\[ v(x) = v_0 + v_1 \cos[\phi(x)] + v_2 \sin[\phi(x)] + \frac{1}{2} v_2^2 \cos^2[\phi(x)] + v_2 \sin[2\phi(x)] \cdots . \]  \hspace{1cm} (14)

This can be rearranged as

\[ v(x) = v_0 + v_1 \cos[\psi(x) + \phi_0] + v_2 \cos^2[\psi(x)] + \cdots , \]  \hspace{1cm} (15)

where \( \psi(x) \) and \( \phi_0 \) are renormalized phases.\textsuperscript{16}

The frequency distribution function for a static one-dimensionally modulated incommensurate system is, in the constant-amplitude approximation, obtained\textsuperscript{12,16} as

\[ f(v) = \frac{\text{const}}{d\nu/dx} + \frac{\text{const}}{(d\nu/d\psi)(d\psi/dx)} . \]  \hspace{1cm} (16)

Singularities will appear in the spectrum when (i) \( d\nu/d\psi \rightarrow 0 \), and/or (ii) \( d\psi/dx \rightarrow 0 \).

In the plane-wave limit \( d\psi/dx = \text{const} \) and the only singularities are associated with \( d\nu/d\psi \rightarrow 0 \). In the multisoliton lattice limit the phase \( \psi \) will be nearly constant in the "commensurate" domains where \( d\psi/dx \rightarrow 0 \), whereas it will vary with \( x \) in the "solitonlike" domain walls where \( d\psi/dx \neq 0 \). The appearance of "commensurate" domains will thus result in the appearance of new "commensurate" lines and in a reduction of the intensity of the incommensurate background and edge singularities.

Expressing \( \psi(x) = \varphi(x) + \phi_0 \), we can rewrite Eq. (4) as

\[ \frac{d\psi}{dx} = \text{const} \times [\Delta^2 + \cos^2(n(\psi - \phi_0)/2)]^{1/2} , \]  \hspace{1cm} (17)

where \( \Delta^2 \) is related to the soliton density \( n_s \) by Eqs. (8b) and (9), with

\[ K(k) = K \left[ \frac{1}{(1 + \Delta^2)^{1/2}} \right] \]

being defined by Eq. (8a). Here \( \Delta^2 \) is determined from the experiment by fitting the observed line shape to Eqs. (16) and (17).

Expression (17) yields up to \( n \) new "commensurate" lines for \( \Delta \rightarrow 0 \) in addition to the incommensurate edge singularities arising from \( d\nu/d\psi \rightarrow 0 \). The new lines will appear for \( \Delta \ll 1 \) when \( \cos^2[n(\psi - \phi_0)/2] = 0 \), i.e., when

\[ \psi = (2m + 1)\pi/n + \phi_0 \]  \hspace{1cm} (18)

In the commensurate phase \( \phi(x) \) and \( \varphi(x) \) become constants which just renormalize the phase shift \( \phi_0 \rightarrow \tilde{\phi}_0 \). Expressing the commensurate wave vector \( q_c \) characterizing a given commensurate phase as

\[ q_c = b^* \frac{M}{N} , \]  \hspace{1cm} (19)
where $\mathbf{b}^*$ is a reciprocal-lattice vector of the high-temperature phase and $M,N$ are integers, relation (15) can be written in the simplest linear case ($v_2 = v_3 = 0$) as

$$v^{(M,N)} = v_0 + v_1 \cos \left[ 2\pi \frac{M}{N} + \tilde{\phi}_0 \right], \quad M = 0, 1, 2, \ldots, N - 1.$$  

(20)

Relation (20) yields the NMR frequencies in a commensurate cell which is $N$ times larger than the high-temperature cell. The frequency distribution is now a sum of $\delta$ functions

$$f(v) = \frac{1}{N} \sum_{M=0}^{N-1} \delta(v - v^{(M,N)})$$  

(21)

yielding $17$ $N$ commensurate instead of the quasicontinuous incommensurate frequency distribution. $16$ The splittings between these lines will vary with $N$ roughly as $\Delta v = 2v_1/\sqrt{N-1}$. The commensurate peaks will be smeared out and indistinguishable from an incommensurate plane-wave-type line shape if the natural linewidth of the individual lines is larger than $\Delta v$.

It should be noted that on going from one commensurate supercell to another in the devil’s-staircase model, $N$ will vary discontinuously whereas the amplitude $A$ and $v_1$ will be continuous. Still another quantity which will vary with $N$ is the commensurability gap in the phase-fluctuation spectrum, $9$

$$\Delta^2 = K^2 N^2 A N^{N/2 - 2}.$$  

(22)

Here $KN$ is of the order of a phonon frequency and as $|A| \leq 1$, the phase-fluctuation gap $\Delta^2$ goes to zero as $N \rightarrow \infty$, i.e., as the truly incommensurate phase is approached.

III. RESULTS AND DISCUSSION

A. Incommensurate or higher-order commensurate phases

The $^{87}\text{Rb} \frac{1}{2} \rightarrow \frac{1}{2}$ NMR lines $4,10$ in $\text{Rb}_2\text{ZnBr}_4$ are significantly broader than in $\text{Rb}_2\text{ZnCl}_4$ and the resolution is not good enough to discriminate $17$ between a true incommensurate phase and a higher-order commensurate phase with $N = 17$.

Except $18$ very close to $T_1$, the modulation wave is static and pinned similarly as in other incommensurate systems. Several arguments which speak for pinning by impurities and against the possibility of a pinning due to the discreteness of the crystal lattice and the existence of a devil's staircase in $\text{Rb}_2\text{ZnBr}_4$ are the following.

(i) The floating $11$ of the modulation wave close to $T_1$ is similar to that in $\text{Rb}_2\text{ZnCl}_4$. $19$

(ii) The phase- and the amplitude-fluctuation branches in $\text{Rb}_2\text{ZnBr}_4$ have been clearly identified. $10$ The phase gap in the incommensurate phase—as measured by the phase-fluctuation induced spin-lattice relaxation rate $4,10$—is of the same order as in $\text{Rb}_2\text{ZnCl}_4$, where it is defect induced.

(iii) In the low-temperature part of the incommensurate phase, “commensurate” peaks appear, indicating the transition from the plane wave to the multisoliton lattice-type modulation regime. If these peaks indicated transitions from one commensurate supercell to another, the changes would be less continuous than observed and would, moreover, be accompanied by jumps in the phase-fluctuation-induced $T_1$ as observed $20$ in $[\text{N(CH}_3)_4]_2\text{ZnCl}_4$ but not in $\text{Rb}_2\text{ZnBr}_4$.

(iv) The incommensurate-commensurate transition in $\text{Rb}_2\text{ZnBr}_4$ is accompanied by a jump in the phase-fluctuation-induced $T_1$, which is of the same order as in $\text{Rb}_2\text{ZnCl}_4$. $17,20$

We thus believe that the modulation wave in $\text{Rb}_2\text{ZnBr}_4$ is pinned by defects and that the observed behavior $5,6$ close to the incommensurate-commensurate transition is due to a large number of coexisting long-period phases or domains due to pinning by frozen impurities, $15$ which destroy long-range order in the strict sense. The fact that in some samples the incommensurate-commensurate transition could not be observed at all supports this conclusion.

B. The soliton density and its $T$ dependence

The temperature dependence of the line splitting is shown in Fig. 4 for $a_1 \text{H}_2 \parallel b, H_0 = 162^\circ$. The relation between the nuclear resonance frequency and the nuclear displacements is here such that the linear term is dominant. The splitting can be fitted by $v_1 = 35$ kHz and $\tilde{\phi}_0 = 0$. A comparison between the experimental and theoretical line shapes is given in Fig. 5 for $\text{Rb}(2)$. The commensurate lines appearing at the center of the spectrum are clearly visible and gradually increase in intensity on approaching $T_c$, whereas the other two groups of commensurate lines merge with the edge singularities. The critical exponent $\beta$ is $0.36 \pm 0.04$ and $n_z$ has qualitatively—though not quantitatively—a similar behavior as in $\text{Rb}_2\text{ZnCl}_4$. $8,9$ On cooling $n_z$ is nonzero at $T_c$, demonstrating the existence of metastable randomly pinned solitons which persist even below $T_c$. The density of pinned solitons at $T_c$ is considerably higher here than in $\text{Rb}_2\text{ZnCl}_4$. $8,9$ This seems to be due to a greater concentration of impurities (i.e., CI admixtures), thus suggesting that the metastable chaotic phase $14$—intermediate between the incommensurate and commensurate phases—is defect induced.

II. RESULTS AND DISCUSSION

A. Incommensurate or higher-order commensurate phases

The $^{87}\text{Rb} \frac{1}{2} \rightarrow -\frac{1}{2}$ NMR lines $4,10$ in $\text{Rb}_2\text{ZnBr}_4$ are significantly broader than in $\text{Rb}_2\text{ZnCl}_4$ and the resolution is not good enough to discriminate $17$ between a true incommensurate phase and a higher-order commensurate phase with $N = 17$.

Except $18$ very close to $T_1$, the modulation wave is static and pinned similarly as in other incommensurate systems. Several arguments which speak for pinning by impurities and against the possibility of a pinning due to the discreteness of the crystal lattice and the existence of a devil's staircase in $\text{Rb}_2\text{ZnBr}_4$ are the following.

(i) The floating $11$ of the modulation wave close to $T_1$ is similar to that in $\text{Rb}_2\text{ZnCl}_4$. $19$

(ii) The phase- and the amplitude-fluctuation branches in $\text{Rb}_2\text{ZnBr}_4$ have been clearly identified. $10$ The phase gap in the incommensurate phase—as measured by the phase-fluctuation induced spin-lattice relaxation rate $4,10$—is of the same order as in $\text{Rb}_2\text{ZnCl}_4$, where it is defect induced.

(iii) In the low-temperature part of the incommensurate phase, “commensurate” peaks appear, indicating the transition from the plane wave to the multisoliton lattice-type modulation regime. If these peaks indicated transitions from one commensurate supercell to another, the changes would be less continuous than observed and would, moreover, be accompanied by jumps in the phase-fluctuation-induced $T_1$ as observed $20$ in $[\text{N(CH}_3)_4]_2\text{ZnCl}_4$ but not in $\text{Rb}_2\text{ZnBr}_4$.

(iv) The incommensurate-commensurate transition in $\text{Rb}_2\text{ZnBr}_4$ is accompanied by a jump in the phase-fluctuation-induced $T_1$, which is of the same order as in $\text{Rb}_2\text{ZnCl}_4$. $17,20$

We thus believe that the modulation wave in $\text{Rb}_2\text{ZnBr}_4$ is pinned by defects and that the observed behavior $5,6$ close to the incommensurate-commensurate transition is due to a large number of coexisting long-period phases or domains due to pinning by frozen impurities, $15$ which destroy long-range order in the strict sense. The fact that in some samples the incommensurate-commensurate transition could not be observed at all supports this conclusion.

B. The soliton density and its $T$ dependence

The temperature dependence of the line splitting is shown in Fig. 4 for $a_1 \text{H}_2 \parallel b, H_0 = 162^\circ$. The relation between the nuclear resonance frequency and the nuclear displacements is here such that the linear term is dominant. The splitting can be fitted by $v_1 = 35$ kHz and $\tilde{\phi}_0 = 0$. A comparison between the experimental and theoretical line shapes is given in Fig. 5 for $\text{Rb}(2)$. The commensurate lines appearing at the center of the spectrum are clearly visible and gradually increase in intensity on approaching $T_c$, whereas the other two groups of commensurate lines merge with the edge singularities. The critical exponent $\beta$ is $0.36 \pm 0.04$ and $n_z$ has qualitatively—though not quantitatively—a similar behavior as in $\text{Rb}_2\text{ZnCl}_4$. $8,9$ On cooling $n_z$ is nonzero at $T_c$, demonstrating the existence of metastable randomly pinned solitons which persist even below $T_c$. The density of pinned solitons at $T_c$ is considerably higher here than in $\text{Rb}_2\text{ZnCl}_4$. $8,9$ This seems to be due to a greater concentration of impurities (i.e., CI admixtures), thus suggesting that the metastable chaotic phase $14$—intermediate between the incommensurate and commensurate phases—is defect induced.

![FIG. 4. Temperature dependence of the splitting of the $^{87}\text{Rb} \frac{1}{2} \rightarrow -\frac{1}{2}$ spectra in $\text{Rb}_2\text{ZnBr}_4$ at an orientation where the linear term is dominant.](image-url)
The temperature dependence of the soliton density in Rb₂ZnBr₄ (Fig. 6) is qualitatively similar to the one in Rb₂ZnCl₄ but there are several important differences:

(i) The soliton density $n_s$ in Rb₂ZnBr₄ is practically constant and equal to the plane-wave modulation value $0.97\pm0.03$ within a temperature interval of more than 100 K, i.e., from $T_f\approx80$ to $-40$°C in sharp contrast to Rb₂ZnCl₄, where it continuously varies with temperature.

(ii) The $^{87}$Rb $\frac{1}{2}\rightarrow-\frac{1}{2}$ NMR lines measured by the spin-echo techniques are much broader than in Rb₂ZnCl₄, thus showing the presence of impurities. In addition to the lines shown in Fig. 5, there is a broad background due to Rb nuclei in the vicinity of defects.

(iii) Close to $T_c$ in the $I$ phase, as well as below $T_c$ in the commensurate phase, a large thermal hysteresis of $10-15$ K (Fig. 6) is observed. On cooling the lowest observed value of $n_s$ at $T_c$ is 0.65, whereas the value of $n_s$ at $T_c$ on heating from low $T$ is about 0.5. Here $T_c$ is determined by the jump¹⁰ in $T_1$. The $n_s$ values are as well rather high if one cools the sample below $T_c$, demonstrating the presence of a metastable chaotic phase with randomly pinned solitons similar to the one observed¹⁹ in Rb₂ZnCl₄.

The differences between the present $n_s$ results and the results of Ref. ¹⁰ are mainly due to the fact that in Ref. ¹⁰ the soliton density was determined from the intensity of the commensurate lines and not from a line-shape analysis.
