Abstract. *Sphagnum* peatlands are important ecosystems in the methane cycle. Methanotrophs living inside the dead hyaline cells or on the *Sphagnum* mosses are able to act as a methane filter and thereby reduce methane emissions. We investigated in situ methane concentrations and the corresponding activity and diversity of methanotrophs in different *Sphagnum* dominated bog microhabitats. In contrast to the Northern Hemisphere peat ecosystems the temperate South American peat bogs are dominated by one moss species; *Sphagnum magellanicum*. This permitted a species-independent comparison of the different bog microhabitats. Potential methane oxidizing activity was found in all *Sphagnum* mosses sampled and a positive correlation was found between activity and in situ methane concentrations. Substantial methane oxidation activity (23 µmol CH₄ gDW⁻¹ day⁻¹) was found in pool mosses and could be correlated with higher in situ methane concentrations (>35 µmol CH₄ l⁻¹ pore water). Little methanotrophic activity (<0.5 µmol CH₄ gDW⁻¹ day⁻¹) was observed in living *Sphagnum* mosses from lawns and hummocks. Methane oxidation activity was relatively high (>4 µmol CH₄ gDW⁻¹ day⁻¹) in *Sphagnum* litter at depths around the water levels and rich in methane. The total bacterial community was studied using 16S rRNA gene sequencing and the methanotrophic communities were studied using a *pmo*⁴ microarray and a complementary *pmoA* clone library. The methanotrophic diversity was similar in the different habitats of this study and comparable to the methanotrophic diversity found in peat mosses from the Northern Hemisphere. The *pmoA* microarray data indicated that both alpha- and gammaproteobacterial methanotrophs were present in all *Sphagnum* mosses, even in those mosses with a low initial methane oxidation activity. Prolonged incubation of *Sphagnum* mosses from lawn and hummock with methane revealed that the methanotrophic community present was viable and showed an increased activity within 15 days. The high abundance of methanotrophic *Methylocystis* species in the most active mosses suggests that these might be responsible for the bulk of methane oxidation.
1 Introduction

Carbon dioxide and methane are important greenhouse gases and their concentrations are rising rapidly since industrial times (Forster et al., 2007). Methane and carbon dioxide emissions from peatlands contribute to the greenhouse effect, but for good prediction models more information is needed about the carbon cycle in these ecosystems. Microorganisms play an important role in the biogeochemical cycles of these peatlands and the knowledge about their diversity can help to improve our understanding of the carbon and nutrient turnover. Within peat ecosystems methane serves as an important carbon source for methane oxidizing bacteria; methanotrophs (Raghoebarsing et al., 2005; Kip et al., 2010; Larmola et al., 2010). Methanotrophs were found to be present on or inside the dead hyaline cells of Sphagnum mosses and act as a filter for methane, thereby recycling carbon of the system and reducing methane emissions (Raghoebarsing et al., 2005; Kip et al., 2010).

Peat bogs are a harsh environment for microbes to live in because of the low pH (around 4.5) and the low nutrient content. Microbial and methanotrophic communities have been studied in a few Sphagnum dominated peat bogs (Dedysh, 2009; Opelt and Berg, 2004; Kip et al., 2011a). The microbial communities can be investigated with molecular tools based on the bacterial 16S rRNA genes (Stackebrandt and Goebel, 1994), while methanotrophic communities can be characterized using functional genes like the methane monoxygenase genes, pmoA and mmoX (Murrell and Jetten, 2009). These genes encode subunits of the methane monoxygenase enzyme, which catalyses the first step in the methane oxidation pathway and can only be found in methanotrophs. A fast screening tool to study the diversity of methanotrophs is a pmoA based microarray that can be used to analyse the methanotrophic community of an ecosystem (Bedrossy et al., 2003).

Methanotrophs occur within the Proteobacteria, NC10 phylum and the Verrucomicrobia (Op den Camp et al., 2009; Conrad, 2009; Ettwig et al., 2010). The proteobacterial methanotrophs have been intensively studied and have been detected in peat ecosystems (Dedysh, 2009). Unfortunately, current molecular techniques designed for conventional methanotrophs are not able to detect the verrucomicrobial and NC10 methanotrophs yet. Gammaproteobacterial methane-oxidizing bacteria belong to the type I methanotrophs, which use the ribulose monophosphate pathway for formaldehyde fixation. The type II methanotrophs belong to the Alphaproteobacteria, which use the serine pathway for formaldehyde fixation. This group includes the Methylocystis-Methylosinus genera and the acidophilic methanotrophs of the genera Methylocella, Methylocapsa and Methyloferula (Vorobev et al., 2010; Dedysh, 2009; Conrad, 2009). Methylocella species were the first facultative methanotrophs described (Dedysh et al., 2000), but recently also other facultative Methylocystis and Methylocapsa species were isolated (Im et al., 2010; Dunfield et al., 2010; Belova et al., 2011). These facultative methanotrophs have been shown to be able to survive a long period without methane in the presence of acetate, an important carbon source in peat ecosystems (Belova et al., 2011).

Most studies on methanotrophy in peatlands have been performed in the Northern Hemisphere (Dedysh, 2009) and peatlands in the Southern Hemisphere have so far received hardly any attention. South American peat lands are remote areas without human influence and have many ecological interesting features (Grootjans et al., 2010; Blanco and de la Balze, 2004). In the Northern Hemisphere many different Sphagnum species occur that cover the different hydrological niches, such as pools (wet), lawns (intermediate) and hummocks (dry), in South American peatlands only one moss species, Sphagnum magellanicum, frequently dominates these different habitats. The presence of only one moss species enables species-independent analyses of different peat habitats.

The present study describes methane oxidation activity in S. magellanicum sampled from various habitats in two different peat bogs in Tierra del Fuego, Argentina. Methanotrophic activity was studied along a gradient of methane availability. The methanotrophic communities of S. magellanicum mosses from the different micro habitats in one peat bog were investigated using a pmoA microarray and (pmoA and 16S rRNA) clone libraries.

2 Materials and methods

2.1 Study sites description

We studied two different sites: a pure Sphagnum bog, called “high CH₄” bog (54°45′S; 68°20′W, 200 m a.s.l.) and a mixed-cushion bog peatland, called “low CH₄” bog (54°58′S; 66°44′W, 40 m a.s.l.). Annual average daily air temperatures are 5–6 °C with cold austral summers around 9 °C. July is usually the coldest month with mean temperature of 2 °C. At both bogs soil temperature is relatively low and stable throughout the growing season decreasing from 8–12 °C at 5 cm below surface to 4–8 °C at 100 cm depth. The Sphagnum bog was dominated by Sphagnum magellanicum (Brid) with less than 1 % cover of vascular plants like Empetrum ssp., Nothofagus ssp., Rostkovia ssp., Carex ssp., Marsippospermum ssp. and Tetrocion ssp. Sphagnum magellanicum occupies all hydrological niches from pool to hummocks rising up to 1 m above the summer water table. Other Sphagna like Sphagnum falcatus (S. cuspidatum coll.) and Sphagnum cuspidatum co-exist only in pools (Kleinebecker et al., 2007). In poor fens Sphagnum fimbriatum can be found next to S. magellanicum (Grootjans et al., 2010). In contrast, the mixed-cushion bog consists of little Sphagnum magellanicum. The Sphagnum mosses occupy margins of pools and form also small lawns (few square meters) embedded in a
matrix of evergreen cushion plants (Roig and Collado, 2004). Dominating cushion plants were *Astelia pumila* (Forster f.) Gaudich and *Donatia fasciculares* Forster and Forster covering more than 70%. Also the above mentioned vascular plants were present in the mixed-cushion bog. The soil below cushion plants is densely packed with tap roots (1–2 mm diameter) and fine roots exceeding depths of 120 cm causing thorough methane oxidation (Grootjans et al., 2010; Fritz et al., 2011). Lawns of mixed-cushion bog hosted abundantly vascular plants compared to the *Sphagnum* bog. Pore water reflected acid conditions in both bogs (pH 3.5–4.5). Peatlands studied remained unaffected by anthropogenic alteration such as drainage, agricultural use or elevated atmospheric nutrient deposition.

2.2 Pore water methane concentration, pH measurements and methane emissions

Pore water was sampled at depths of 5–10 cm from pools and lawns prior collecting moss and litter samples for incubation (more details see Fritz et al., 2011). Anaerobic peat water samples were taking using 5 cm ceramic cups (Eijkelkamp Agrisearch Equipment® Giesbeek, the Netherlands), connected to vacuum infusion flasks (40 ml) after sampling 150 ml to exclude internal stagnant sampler water. For deeper (litter) samples we measured methane concentrations at a depth of 30 cm below water level. Values of pH (NBS) were determined after collection using a handheld (Consort® C933, Turnhout, Belgium) and a standard pH electrode (SP10T, Consort®, Turnhout, Belgium). Additional water samples were drawn with 60 ml-syringes.

Details on protocols to estimate methane emissions are given in Fritz et al. (2011). *Sphagnum* samples were taken in December 2007, March 2008 and April 2008. Litter samples (dead plant material forming peat) were taken in April and December 2008. For all the samples the depth below the water table and below the surface at the day of sampling was measured. The depth below surface served as the reference for the depth of the sample below mean summer water table. Negative depths depict submerged samples.

2.3 Methane oxidation and production tests

Whole *Sphagnum* mosses were thoroughly washed and incubated in 120 ml bottles with 1 ml of methane. Methane was measured on a Hewlett-Packard model 5890 gas chromatograph equipped with a flame-ionization detector and a Porapak Q column (80/100 mesh). Methane production tests were performed in 60 ml bottles containing only dinitrogen gas. Methane oxidation tests were performed at 10, 15 and 20°C, in the dark.

2.4 Statistical analysis

Regression analyses (linear model) were performed in R software packages (R Development Core Team, 2010) followed by model justification procedures. We log-transformed potential methane oxidation rates before regression analysis. Multiple regressions were carried out starting with all environmental factors (Table 1) and subsequently simplified until the least adequate model was reached (stepwise backward deletion). We only included potential methane oxidation rates found in samples from patches with living *Sphagnum* (n = 6). Despite the low number of measurements models exhibited well-spread residuals.

2.5 Bacterial and methanotrophic community analysis

*Sphagnum* mosses were washed with sterile demineralized water after sampling and kept frozen at −20°C. Genomic DNA isolation, pmoA microarray and mmoX analysis was performed as described before (Stralis-Pavese et al., 2011; Bodrossy et al., 2003). All pmoA microarray data are available upon request.

For the clone library the PCR amplification of the pmoA gene was performed with two general pmoA gene primers: A682R and A189F (Holmes et al., 1995). All PCRs were performed in a gradient from 50 to 60 degrees and PCR products were combined. All PCR products were purified using the QIAquick PCR Purifications Kit (Qiagen). DNA sequencing was performed with the primers used in the PCR. The pmoA gene primers used were specific only for known methanotrophic *Alpha*- and *Gammaproteobacteria*, primers and were not expected to hybridize with the pmoA gene of methane-oxidizing *Verrucomicrobia*. Therefore we also designed a new primer set based on the pmoA1 and pmoA2 of all three verrucomicrobial methanotrophs [10]: V′pmoA216: 5′-GGAAAGAymGrATGTGGTGGCC-3′ (forward) and V′pmoA622: 5′-GTTTTCnACCAATnCnATyTAYTCAGG-3′ (reverse). Initial validation using a pure culture of *Methyloacidiphilum fumarolicum* SolV resulted in a product of the expected size and other proteobacterial cultures, including all isolated methanotrophs described in Kip et al. (2011b) were tested, did not result in a PCR product.

The pGEM-T Easy Vector System Kit (Promega) was used for ligation of the pmoA gene amplifications. Ligation was performed as prescribed by the manufacturer. pmoA gene ligation mix was transformed by heat shock exposure to XL-1 Blue competent *E. coli* cells, constructed as described by Inoue et al. (1990). pDNA with ligated pmoA gene was isolated with the E.Z.N.A.™ Plasmid Miniprep Kit (EZNA™). The pmoA gene sequences were sequenced with M13 forward and reverse primers (Invitrogen™), targeting vector sequences adjacent to the multiple cloning site. pDNA sequencing was performed by the sequencing facility of the UMC Sint Radboud, Nijmegen. Clone library sequences and their closes relatives were analyzed using MEGA version 4.
might be explained by methanotrophic consumption, thereby significantly reducing methane emissions to the atmosphere. Therefore mosses were tested for methane oxidizing activity.

3.2 Methane oxidizing activity tests

Initial methane oxidizing activities of *Sphagnum* mosses from the two different peat ecosystems were determined (Table 1). Highest activity (23.5 µmol CH$_4$ g DW$^{-1}$ day$^{-1}$) was found in mosses collected from methane rich pools (35 µM CH$_4$). Low methane oxidizing activity was found in *Sphagnum* mosses from aerated habitats like hummock and lawns that were typically depleted in methane (<2 µM CH$_4$). In the “low CH$_4$” bog the pool was depleted in methane and the methane oxidizing activity was low (0.5 µmol CH$_4$ g DW$^{-1}$ day$^{-1}$) and comparable to the drier habitats like lawns and hummocks. The results show a clear positive correlation between the methane concentration in the pore water and the initial potential methane oxidation rates of the tested mosses (Fig. 1). Methane pore water concentration could explain 68 % ($p < 0.05$; $F = 11.8$; d.f. 4) of the variation found in the potential methane oxidation rates along the different micro habitats of *Sphagnum magellanicum*. The combined variation of methane porewater concentration together with height of the mosses above the water table accounted for 94 % of variation found in the potential methane oxidation rates ($p < 0.01$; $F = 39.0$; d.f. 3). Potential methane oxidation rates at 20 °C were twice as high as rates at 10 °C, resulting in a Q10 of around 2.

Since submerged *Sphagnum* mosses showed highest methane oxidizing activity, correlating with the highest methane pore water concentration, we sampled *Sphagnum* litter (dead plant material forming peat) below the water level from the lawn and hummock in the “high CH$_4$” bog and tested them for methane oxidation and production (Table 1). These subsurface samples showed a high pore water methane concentration and both methane oxidation and methane production were found in these samples. The potential methane

---

### Table 1. Overview of ecological parameters obtained at the “high CH$_4$” bog and “low CH$_4$” bog. Sampling depths relative to water levels are positive when the sample was taken above the water level (living *Sphagnum* moss) and negative when the sample was taken from below the water level (litter). Sample depths are indicated as measured at the day of sampling and relative to the mean summer water level. ND indicates no data. Water content is expressed in % of the wet weight.

(Tamura et al., 2007). All sequences were aligned automatically using the alignment tool of MEGA4 (ClustalW). Phylogenetic trees were calculated using the Neighbor-joining method. The sequences of the *pmoA* gene clones were deposited in the Genbank database under accession numbers JF907375–JF907390.
Sphagnum mosses from lawn and hummock sites showed induced methane oxidation in lawn and hummock. The "low CH$_4$" sample needed at least three weeks of incubation with "high CH$_4$" ing to growth of methanotrophs (data not shown). The low potential methane oxidation rates in comparison to pool samples "high CH$_4$" bog. Activities were measured at two different temperatures: 10 and 20°C.

oxidation rates of Sphagnum litter were substantial (3.8 to 10.5 µmol CH$_4$ gDW$^{-1}$ day$^{-1}$). At even greater depths (55 cm below the water table) potential methanotrophic activity was found. Measured methane oxidation rates are not representative in situ rates, due to the high oxygen concentration during incubation. Potential methane production rates were higher at 55 cm than at 5 cm in the lawn Sphagnum litter and were around 0.5 µmol CH$_4$ gDW$^{-1}$ day$^{-1}$ at 10°C at 55 cm. Submerged Sphagnum litter from the hummock showed a rather low potential methane production rate (0.01 µmol CH$_4$ gDW$^{-1}$ day$^{-1}$ at 10°C).

### 3.3 Induced methane oxidation in lawn and hummock

Sphagnum mosses from lawn and hummock sites showed low potential methane oxidation rates in comparison to pool mosses. Water levels and methane concentrations fluctuate in the lawns and parts can be inundated or dry in different periods of the year. In the Patagonian hummocks mosses grow up to 1 m above the water level and are very dry. Nevertheless, upon prolonged incubation of lawn and hummock mosses, methane oxidation increased exponentially pointing to growth of methanotrophs (data not shown). The "high CH$_4$" bog lawn mosses showed a threefold increase in methane oxidation potential within 2 weeks and the hummock sample needed at least three weeks of incubation with methane. The "low CH$_4$" lawn mosses needed almost one month to show a threefold increase in methane oxidation.

### 3.4 Bacterial and methanotrophic community analysis

So far bacterial diversity studies in peatlands have been limited to sites in the Northern Hemisphere. We tried to get an insight into the diversity of bacteria and especially of methanotrophs in the Sphagnum mosses and peat litter from the different habitats in the Southern Hemisphere. Furthermore, the diversity between the same moss species growing in different micro-habits was compared. A 16S rRNA clone library analysis was performed using mosses from the pool in the "high CH$_4$" bog, see Fig. 2 and the Supplementary Material for more details. The 16S rRNA gene clone libraries showed a very diverse set of bacteria to be present inside or on Sphagnum mosses. The Proteobacteria represented the biggest phylum (42 %), with a majority of Alpha- and Betaproteobacteria. Next to that the Acidobacteria (28 %) and Verrucomicrobia (13 %) were present in high numbers within the Patagonian Sphagnum mosses.

In order to investigate the presence of methanotrophs the unique functional gene marker pmoA, coding for a subunit of the methane monoxygenase gene was used. A pmoA clone library showed the presence of Methylcystis-Methylosinus and Methylococci species (Supplementary Material Fig. S1). For a more complete methanotrophic diversity analysis a microarray was performed. This pmoA microarray (Bodrossy et al., 2003) represents different pmoA gene sequences of cultured and non-cultured methanotrophs. pmoA PCR products from the pool and hummock samples and the litter samples of lawn (~55 cm below the water level) and hummock (~10 cm below the water level) from the “high CH$_4$” bog were hybridized onto the microarray. All samples showed a rather similar methanotrophic community, as revealed by a similar hybridization patterns on the microarray of the different samples (Fig. 3). The microarray results showed abundance of both type I (Gammaproteobacteria) and type II (Alphaproteobacteria) methanotrophs and a high methanotrophic biodiversity. The submerged Sphagnum mosses showed a higher hybridization with the type II probes over type I. The pool mosses and litter samples showed a
similar hybridization pattern indicating a similar methanotrophic community at the surface and below the water table. The type II probes showed that both *Methylocystis* spp. and *Methylosinus* spp. were present in all the *Sphagnum* mosses, although the hummock *Sphagnum* mosses showed a much lower abundance and also a lower methane oxidation activity compared to all other samples. The probe Peat264, targeting a group of uncultivated peat-related alphaproteobacterial methanotrophs also showed a strong hybridization.

The microarray also showed a strong signal with the gamma-proteobacterial probes targeting the genera *Methylomonas*, *Methylobacter* and *Methylocystis*. A broad diversity of *Methylomonas* and *Methylobacter* was detected. The *pmo*A clone library (see above) revealed two *Methylomonas*-related sequences. The specific probes, which target the type Ib (type X) methanotrophs (including the thermotolerant and thermophilic gammaproteobacterial genera *Methylococcus* and *Methylocauldum* as well as environmental clades) showed a weaker signal, but still indicated a diverse community across the analyzed samples. The viability of the methanotrophs inside hummock and lawn mosses was obvious after longer incubation times in the methane consumption experiments (see above). The microarray also confirms the presence of methanotrophs in the hummock mosses which showed very low initial methane oxidation. Unfortunately the lawn mosses did not yield enough PCR product to perform microarray analysis. *Methylocella* spp., which are commonly found in Northern peatlands (Dedysh et al., 2004; Dedysh et al., 2000) and the recently discovered *Methyloferula stellata* (Vorobev et al., 2010) are the only known methanotrophs that do not have a *pmo*A gene and are therefore not detected in this microarray. These genera do have a soluble methane monooxygenase enzyme from which the encoding gene (*mmox*) can be also be used for phylogenetic analysis (Auman et al., 2000; Miguez et al., 1997). Searching for *Methylocella* spp. by screening with a *mmox*-based PCR on the two pool samples did not result in any PCR product (Kip et al., 2010), indicating *mmox*-possessing methanotrophs are not abundantly present or that the PCR primers are not suitable.

The PCR primers used thus far are not able to amplify verrucomicrobial *pmo*A genes (Pol et al., 2007). We designed new primers based on currently available verrucomicrobial sequences (see Materials and Methods) but were not able to obtain a PCR product using these primers.

### 4 Discussion

This study revealed a high activity and diversity of methanotrophic bacteria in Patagonian *Sphagnum* bogs. High potential rates of methane oxidation coincided with substantially reduced methane emissions especially at low water levels, reflecting an important role of the methanotrophs in reducing emissions at these sites. Methane oxidation by the living parts of the *Sphagnum* moss was found to be dependent on the availability of methane. This availability determines the presence and activity of methanotrophs and the water level is an important regulator as only under water logged conditions high concentrations of methane can be expected. If the mosses grow high above the water level, methane will already have been oxidized by bacteria attached to the aerobic *Sphagnum* litter before it reaches the living parts. However, if methane concentrations are low, like in the “low CH₄” bog, overall methanotrophic activity is low and independent of the water level. Statistical analyses also show a correlation of methane oxidation with methane pore water concentration rather than water level. Water level has been hypothesized to be the key environmental factor regulating methanotrophy in *Sphagnum* (Larmola et al., 2010), but our results suggest...
the methane pore water concentration to be the main driver, as was also suggested in other studies on peat ecosystems (Basiliko et al., 2007).

Living mosses collected from lawns and hummocks showed a low potential methane oxidation rate, but litter (dead parts) sampled at and below the water level showed a much higher rate. In addition, also methane production was found in these samples. The methane production and consumption activities at the same depths indicate the co-existence of contrasting micro-sites. The activity of methanotrophs and methanogens around the water level are influenced by fluctuating water levels over the year in a peat ecosystem, which makes the litter sometimes anoxic and sometimes oxic (Lai, 2009). Under both conditions microbes take their opportunities and this shows that there is not a real fixed aerobic-anaerobic interface restricting the microbial activities, like e.g. in a rice field (Luke et al., 2010). Potential methane oxidation has also been reported in Northern peat bogs in depth samples that were anoxic under field conditions (Edwards et al., 1998).

The microbial community inside and attached to Patagonian Sphagnum mosses is comparable to previously investigated peat soils from the Northern Hemisphere (Kulichevskaya et al., 2007; Dedys et al., 2006). Most of the 16S rRNA clones showed sequence similarity to isolates or environmental samples originating from Siberian acidic peat bogs. This points to the presence of similar bacterial communities in peatlands from both the Northern and Southern Hemisphere and implies that there is no big geographical difference.

So far, acidophilic methanotrophs belong to the Proteobacteria and Verrucomicrobia (Op den Camp et al., 2009; Conrad, 2009; Dedys, 2009). Both groups were found in abundance in the 16S rRNA clone library, but none of the 16S rRNA sequences were closely related to currently known methanotrophs.

The pmoA clone library and microarray both showed the presence of Methylocystis and Methylomonas, which were the two families that were found to be abundant in and on Sphagnum mosses from a Dutch peat bog (Kip et al., 2011a). Recently several representatives of both families were isolated in pure culture from Sphagnum mosses and characterized (Kip et al., 2011b). The total pmoA diversity of the Sphagnum mosses was very high compared to other studies using the same microarray on peat soils (Chen et al., 2008), peat based upland soils (Cébron et al., 2007) and rice fields (Vishwakarma et al., 2009), but quite similar to the methanotrophic communities in Sphagnum mosses from other peat bogs around the world (Kip et al., 2010). Here however we have shown that all the microhabitats were showing a comparable methanotrophic community composition, considering the origin of all the different micro habitats where methane and oxygen concentrations are very different.

No mmoX possessing methanotrophs were detected despite using different mmoX primer combinations (Miguez et al., 1997; McDonald et al., 1995; Auman et al., 2000). This might indicate a low abundance of Methylomonas species. However, several Methylomonas and Methylocystis spp. also possess the mmoX gene but remained undetected. This might be caused by a limited detection range for the primers used or because the methanotrophs present indeed do not possess a mmoX gene. For future studies it could be worthwhile to test the recently described more specific Methylocella spp. real time quantitative mmoX PCR primers (Rahman et al., 2011).

There was no detection of Verrucomicrobial methanotrophs using newly designed primers. This could indicate the absence of these type of methanotrophs or they remained undetected because of the limited sequence database, which narrows the detection range of the primers.

Despite the low potential methane oxidation rates of the dry hummock, the microarray analysis showed that methanotrophs were present. They were mostly probably present in very low densities, but viable, since they respond to increased availability of methane by building up an active population. Methanotrophs present in the lawn mosses reacted faster upon prolonged incubation compared to those from hummocks, which is most probably due to the in situ fluctuations in methane availability which are bigger in lawns located closed to the mean water level, than in hummocks.

The type II probes of the microarray showed that both Methylocystis sp. and Methylosinus sp. were present in all the Sphagnum mosses, although the mosses from the hummock showed a much lower abundance, which coincides with a lower methane oxidation activity compared to all other samples. The high abundance of Methylocystis spp. in the most active mosses indicates they are probably the key players in this ecosystem. The capacity to use acetate as an additional carbon source, to fix nitrogen and to consume methane at both high and low concentrations by several Methylocystis spp. might represent an important part of the survival strategy of this kind of methanotrophs in peat lands (Belova et al., 2011; Buckley et al., 2008; Im et al., 2010). This might explain why they are found in abundance in this Sphagnum dominated peatland and other ecosystems. However to test if the species present in this system are indeed capable of the above mentioned traits it is necessary to isolate and test the important methanotrophic players of the system.
