Abstract

We report the detailed long-term reconstitution of B-lymphocyte subpopulations, immunoglobulins, and specific antibody production after two courses of rituximab in a young, previously healthy girl with steroid-dependent autoimmune hemolytic anemia. B-lymphocyte subpopulations were surprisingly normal directly after reconstitution. However, there was a slower reconstitution after the second rituximab course, especially of non-switched and switched memory B-lymphocytes, and a temporary decline in IgM below age-matched reference values.

Introduction

Rituximab is increasingly used in the treatment of various hematological malignancies and, more recently, autoimmune diseases like autoimmune hemolytic anemia (AIHA).1 Rituximab is a monoclonal antibody that reacts with the CD20 antigen, which is expressed on pre-B and mature B-lymphocytes, but not on plasma cells. B-lymphocytes play an important regulatory and potentially pathogenic role in autoimmune diseases through antibody-independent mechanisms like antigen presentation, T-lymphocyte activation, and the production of cytokines and chemokines.2,3 They are also the precursors of (auto)antibody-producing plasma cells. Depletion of B-lymphocytes is therefore likely to interfere with the complex (auto)immune process, but the exact mechanism of its effect on autoimmune diseases is not yet fully understood.4

Treatment with rituximab results in a rapid and sustained depletion of B-lymphocytes. There are detailed reports on the rate and phenotype of B-lymphocyte subpopulation recovery after rituximab treatment in adults.5-12 After B-cell depletion immature B-lymphocytes reappear first, followed by naïve B-lymphocytes; CD27+ memory B-lymphocytes may remain reduced up to 2 years after rituximab treatment.5,8

It would be expected that depletion of CD20+ B-lymphocytes has direct effects on antibody production, and indirect effects on cellular immunity. Indeed, hypogammaglobulinemia requiring substitution was recently described in a child with repeated rituximab treatment for idiopathic thrombocytopenic purpura and underlying autoimmune lymphoproliferative disease.11 However, until now large numbers of serious infectious complications of rituximab treatment have not been described,4 perhaps because antibody-producing plasma cells are spared.

In this paper, we give a detailed description of the reconstitution of B-lymphocyte subpopulations, immunoglobulins (Igs), and specific antibody production after repeated treatment with rituximab in a young, previously healthy, girl with steroid-dependent AIHA.

Materials and Methods

Patient

In August 2004, a previously healthy 13-months-old girl presented in our hospital with AIHA which turned out to be steroid-dependent. Aspecific IgG autoantibodies were strongly positive. In August 2005, she was treated with rituximab (4x375 mg/m², 1 week apart). Human anti-chimeric antibodies (HACAs) were measured once and found negative. Subsequently, steroids could be tapered and stopped 11 months after the first rituximab treatment, in July 2006. A few weeks later, she suffered a relapse and steroids were restarted, and a second course with 4 gifts of rituximab (375 mg/m², 1 week apart) was administered. Hereafter, the steroid dose was slowly reduced again, and 11 months after the second treatment with rituximab, in July 2007, at the age of 4 years, steroids were stopped completely. In 2011, at almost 8 years of age, there were still no signs of relapse. Aspecific IgG autoantibodies remained negative. She did not suffer from any significant infections. The clinical course of this girl is illustrated in Figure 1.

Preceding rituximab treatment, but while on steroids, vaccination status was optimised using Prevenar twice (Wyeth) followed by Pneumovax (Sanofi Pasteur MSD) for S. pneumoniae, and NeisVacC (Baxter) and MeningovaxAC (Sanofi Pasteur MSD) for S. meningitidis. This was considered important, because both rituximab and prolonged steroid treatment might compromise immunity. After 2.5 years, Pneumovax and Mencevax ACWY (Glaxo Smith Kline) vaccinations were given. Diphtheria - tetanus - inactivated poliomyelitis (DTP-NVI) vaccination was given at the age of four. According to the regular Dutch immunisation schedule (Figure 1).

Peripheral blood samples were taken at multiple time points (t = 0, 8, 14, 21, 56, 110, 202, 321, 383, 396, 403, 410, 417, 446, 530, 614, 718, 816, 1085 days after the first rituximab dose, indicated with arrows in Figure 1) to establish the reconstitution of B-lymphocyte subpopulations, Ig titers and specific antibody production.

Immunophenotyping

Four-color flow cytometric immunophenotyping was performed using the lys e and wash whole-blood method. Aliquots of ethylene diamine-etaetetic (EDTA) blood (50 μL) were incubated for 15 min at room temperature in the dark with the following monoclonal antibodies: isotype control gamma 1 conjugated to fluorescein isothiocyanate (FITC) (Becton Dickinson, San Jose, CA, USA (BD)), isotype control gamma 2a conjugated to phycoerythrin (PE) (BD), CD3-FITC (Immuo Quality Products, Groningen, The Netherlands (IQP)), CD3 conjugated to allophyococyanin (APC) (BD), CD3 conjugated to PE-Cyanin5 (PE-Cy5) (Couler Immunotech, Marseille, France (CI)), CD4-PE (IQP), CD4-PE-Cy5 (CI), CD5-FITC (BD), CD8-PE (IQP), CD8 conjugated to peridinin chlorophyll protein cyanin 5.5 (PerCP-Cy5.5) (BD), CD10-APC (BD), CD16/56-PE (BD), CD19-PE (BD), CD19-PE-Cy5 (CI), CD19-PerCP-Cy5.5 (BD), CD20-FITC (BD), CD21-PE (BD), CD25-FITC (CI), CD27-FITC (BD), CD27-PE (BD), CD45RA-PE (CI), CD45RO-FITC (BD or IQP), IgG-FITC (SouthernBiotech, Birmingham, USA), and IgM-FITC (Sanofi Pasteur Marnes-La-Coquette, France). To eliminate immunoglobulins, aliquots destined for anti-IgM and anti-IgD were washed three times before staining.

Erythrocytes were lysed using FACSLyse solution (BD) according to the manufacturer’s protocol. The cells were washed twice with 0.5% bovine serum albumin/phosphate-buffered saline. Analysis was performed using CellQuest Pro Software (BD) on a FACSCalibur flow cytometer (BD), which was calibrated according to the guidelines of Kraan et al. The absolute leukocyte count (×10⁹/L) was determined on a Sysmex XE-2100 hematology analyzer (Sysmex, Kobe, Japan). The absolute number (×10⁹/L) of a lymphocyte subpopulation was calculated by multiplying the calculated absolute lymphocyte size (×10⁹/L) with the relative size of the lymphocyte subpopulation (%) within the lymphocyte gate. The values were compared to reference values in healthy children derived from our laboratory.

**Immunoglobulins**

IgG, IgA, IgM, and IgG subclasses were determined by standard nephelometric methods (BNIProspect, Dade Behring, The Netherlands). Specific antibody responses to pneumococcal vaccination were determined by ELISA, diphtheria and tetanus antitoxin antibodies with a toxin-binding inhibition assay.

**Results**

As expected, all peripheral blood B-lymphocyte subpopulations disappeared rapidly upon treatment with rituximab (Figure 2), T-lymphocyte subpopulation and NK-cell counts were not affected (Table 1). After the first rituximab course, B-cells reappeared at t = 110 days, after the second course they reappeared later, at t = 614 (218 days after the second rituximab course). The reappearing cells were mainly naive cells (CD19⁺IgD⁺CD27⁻), around one third were CD5⁺ (Figure 2). After the second course, both non-switched (CD19⁺IgD⁺CD27⁻) and switched (CD19⁺IgD⁻CD27⁺) memory B-lymphocytes reappeared later than after the first course (at t = 110 days after the first course, together with the naive cells, and at 320 days after the second course, which is 102 days after the first naive cells, at t = 718 days (Figure 2). However, switched memory B-lymphocytes were within the age-limits of normal from the moment they reappeared (Table 1). CD21⁺ cells (IgM - and IgM +) repopulated in the same manner as the other B-lymphocyte subpopulations.

IgG, IgA, and IgG subclass levels were unaffected by the rituximab treatment (Table 1), but after the second course, a temporary decrease in IgM was found (0.48 g/L at t = 446 days; 0.23 g/L at t = 530 days; 0.6 g/L at t = 614 days), as has been described before. After both rituximab treatments prednisone was used every other day and slowly tapered until it could be stopped. After the first treatment with rituximab the dosage of prednisone was slightly higher. During that time we didn’t see an effect on immunoglobulins or significant infections. Vaccination responses before the first rituximab course were normal; booster responses after the second course (after t = 1085 days) were normal as well (Table 1), despite the fact that she had been on steroids during the first round of vaccinations.

**Discussion**

We followed a girl with steroid-dependent AIHA who was treated with 4 gifts of rituximab twice. She repopulated mainly with naive B-lymphocytes, around one third CD5⁺ as could be expected for her age. Interestingly, her B-lymphocytes returned to normal faster than described before in both adults and children, but these children had underlying diseases that may have influenced the reconstitution. She did not suffer any significant infections, and responded well to vaccination, despite her prolonged steroid use. During repopulation memory B-lymphocytes peaked just before the relapse in our patient. Increasingly, early relapse of autoimmune diseases like rheumatoid arthritis or SLE are reported in adult patients with a higher number of memory B-lymphocytes in early reconstitution in comparison to patients with later or no relapse. Our case suggests that this relation may also exist in children. After the second rituximab treatment, the reconstitution was somewhat slower in our patient. This has been described by others, suggesting that multiple rituximab courses
