ABSTRACT

Background

Tinnitus is the perception of sound or noise in the absence of an external or internal acoustic stimulation. It is a common and potentially distressing symptom for which no adequate therapy exists.

Objectives

To assess the effectiveness of anticonvulsants in patients with chronic tinnitus.

Search methods

We searched the Cochrane Ear, Nose and Throat Disorders Group Specialised Register, CENTRAL (2010, Issue 2), MEDLINE, EMBASE, bibliographies and additional sources for published and unpublished trials. The date of the most recent search was 26 May 2010.

Selection criteria

We selected randomised controlled trials in patients with chronic tinnitus comparing orally administered anticonvulsants with placebo. The primary outcome was improvement in tinnitus measured with validated questionnaires. Secondary outcomes were improvement in tinnitus measured with self-assessment scores, improvement in global well-being or accompanying symptoms, and adverse drug effects.

Data collection and analysis

Three authors assessed risk of bias and extracted data independently.

Main results

Seven trials (453 patients) were included in this review. These studies investigated four different anticonvulsants: gabapentin, carbamazepine, lamotrigine and flunarizine. The risk of bias of most studies was 'high' or 'unclear'. Three studies included a validated questionnaire (primary outcome). None of them showed a significant positive effect of anticonvulsants. One study showed a significant negative effect of gabapentin compared to placebo with an increase in Tinnitus Questionnaire (TQ) score of 18.4 points (standardised mean difference (SMD) 0.82, 95% confidence interval (CI) 0.07 to 1.58). A second study showed a positive, non-significant effect of gabapentin with a difference compared to placebo of 2.4 points on the Tinnitus Handicap Inventory (THI) (SMD -0.11, 95% CI -0.48 to 0.25). When the data from these two studies are pooled no effect of gabapentin is found (SMD 0.07, 95% CI -0.26 to 0.40).

Anticonvulsants for tinnitus (Review)

Copyright © 2011 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

A third study reported no differences on the THI after treatment with gabapentin compared to placebo (exact numbers could not be extracted from the article).

A meta-analysis of 'any positive effect' (yes versus no) based on a self-assessment score (secondary outcome) showed a small favourable effect of anticonvulsants (RD 14%, 95% CI 6% to 22%). A meta-analysis of 'near or total eradication of tinnitus annoyance' showed no effect of anticonvulsants (risk difference (RD) 4%, 95% CI -2% to 11%). Side effects of the anticonvulsants used were experienced by 18% of patients.

Authors' conclusions

Current evidence regarding the effectiveness of anticonvulsants in patients with tinnitus has significant risk of bias. There is no evidence from studies performed so far to show that anticonvulsants have a large positive effect in the treatment of tinnitus but a small effect (of doubtful clinical significance) has been demonstrated.

PLAIN LANGUAGE SUMMARY

Anticonvulsants for tinnitus

Tinnitus is the perception of sound or noise in the absence of external acoustic stimulation. It is a common and potentially distressing symptom for which no adequate therapy exists. The pathophysiology of tinnitus has been compared to phantom limb pain therefore anticonvulsant drugs have been proposed as a possible therapy.

This review includes seven studies (six low-quality and one high-quality) of four different anticonvulsants (gabapentin, carbamazepine, flunarizine and lamotrigine). We found that anticonvulsants do not have a beneficial effect in the treatment of tinnitus. Side effects of the anticonvulsants used were experienced by 18% of patients.

BACKGROUND

Background

This is one of a number of tinnitus reviews produced by the Cochrane Ear, Nose & Throat Disorders Group. The following paragraphs ('Description of the condition') are partially based on earlier work in the following reviews and reproduced with permission: Baldo 2006; Bennett 2007; Hilton 2004; Hobson 2010; Phillips 2010.

Description of the condition

Tinnitus is a phantom auditory perception of meaningless sound in the absence of an external or internal acoustic stimulation. While for the patient this perception of noise is very real, it can be considered a phantom, or false, perception because there is no corresponding external sound. For the patient it may be trivial or it may be a debilitating condition (Luxon 1993). The characteristics of the perceived sound (description, number, frequency, onset, presence and location of the sound) can vary enormously between

patients. For example, patients may hear a single sound or multiple sounds, it may be perceived in one ear, both ears, within the head or outside the body and the symptom may be continuous or intermittent.

It is important to distinguish between clinically significant and non-significant tinnitus (Davis 2000) and several different classifications have been proposed (Dauman 1992; McCombe 2001; Stephens 1991). Severe tinnitus, defined as tinnitus interfering with the normal way of life, is reported in up to 5% of tinnitus patients (Coles 1984; Davis 2000; Nondahl 2002). It is usually associated with other symptoms, such as hyperacusis and many of these patients also suffer from affective disorders and sleeping problems (Crummer 2004; Henry 2005; Jastreboff 2003; Moller 2003).

Differentiation between tinnitus and somatosounds (perceptions of sound caused by an internal acoustic source, due to either a vascular abnormality or a muscular or anatomical cause such as sound generated by blood flow in or around the ear or unusual activity of middle ear muscles within the middle ear) is important because they have different pathophysiologies and therefore different therapeutic approaches. Somatosounds are usually objective;

they can be detected by an examiner, either unaided or using a listening aid such as a stethoscope or microphone in the ear canal. Somatasounds are much less common than tinnitus. Tinnitus is by definition always subjective, meaning that it cannot be heard by anyone other than the patient, while for the patient this perception of noise is real.

Aetiology

The most common causes of tinnitus are otological disorders, most frequently noise and age-induced sensorineural hearing loss, or other types of sensorineural hearing loss. Conductive hearing loss can also cause tinnitus, sometimes transient. Almost any form of disorder involving the outer, middle or inner ear or the auditory nerve may be associated with tinnitus (Brummet 1980; Shea 1981). However, it is possible to have severe tinnitus with no evidence of any aural pathology. Presumably in these cases there is a moderate degree of aural pathology, but not evident enough to be able to diagnose with current diagnostic methods (audiometry only screens a portion of the auditory function). Non-otological causes of tinnitus have also been described, but the causal relationship is less understood. Conversely, tinnitus can even exist without a peripheral auditory system: when the cochlear nerve is severed patients retain their tinnitus (Baguley 1992). This suggests the fundamental importance of the central auditory pathways in the development or maintenance of the symptom, irrespective of trigger.

Pathophysiology

Over 50 years ago, Heller and Bergman demonstrated that if 'normal' people (with no known cochlear disease) were placed in a quiet enough environment, the vast majority of them would experience sounds inside their head. They concluded that tinnitus-like activity is a natural phenomenon perceived by many in a quiet enough environment (Heller 1953).

Despite the high prevalence and morbidity of tinnitus, its pathophysiology is poorly understood. It is probable that different processes are involved in the generation of tinnitus; for example, when it is transient or chronic or when it is caused by conductive or sensorineural hearing loss. Possible theories on the pathophysiology focus on dysfunction of hair cells, the auditory nerve or central auditory system. In the 'neurophysiological model' of tinnitus (Jastreboff 1990; Jastreboff 2004) it is proposed that tinnitus results from the abnormal processing of a signal generated in the auditory system. This abnormal processing occurs before the signal is perceived centrally. This may result in 'feedback', whereby the annoyance created by the tinnitus causes the individual to focus increasingly on the noise, which in turn exacerbates the annoyance and so a 'vicious cycle' develops. In this model tinnitus could therefore result from continuous firing of cochlear fibres to the brain, from hyperactivity of cochlear hair cells or from permanent

damage to these cells being translated neuronally into a 'phantom' sound-like signal that the brain 'believes' it is hearing.

It is commonly thought that chronic tinnitus (caused by sensorineural hearing loss) is generated in the brain as a result of functional reorganisation of the primary auditory cortex, following damage to the peripheral auditory system (Eggermont 2004). This functional reorganisation would cause the tonotopic maps in the central auditory cortex to alter. This altering of maps has indeed been shown in humans with tinnitus (Muhlnickel 1998). On the neuronal level, it is thought that this functional reorganisation causes an increased spontaneous firing rate of neurons in the auditory cortex and auditory brainstem, and an increased synchronisation of spontaneous activity of cortical neurons (Eggermont 2004; Norena 2003; Ochi 1997). This increase in firing rate and synchronisation would lead to hyperactivity in the central auditory system. This resulting hyperactivity has been shown in functional magnetic resonance imaging (fMRI) research in tinnitus patients (Giraud 1999; Lockwood 1998; Melcher 2000). The mechanism underlying this increase in spontaneous firing rate and synchronisation is thought to be reduced inhibition, which is the consequence of the decreased output from damaged cochlear regions (Eggermont 2004; Salvi 2000).

The relationship between the symptom of tinnitus and the activity of the prefrontal cortex and limbic system has been emphasised. The limbic system mediates emotions. It can be of great importance in understanding why the sensation of tinnitus is in many cases so distressing for the patient. It also suggests why, when symptoms are severe, tinnitus can be associated with major depression, anxiety and other psychosomatic and/or psychological disturbances, leading to a progressive deterioration of quality of life (Lockwood 1999; Sullivan 1989; Sullivan 1992; Sullivan 1993).

Prevalence

Epidemiological data reports are few. Reports show that tinnitus is common, affecting approximately 7% to 19% of the adult population (Chung 1984; Coles 1984; Davis 1989; Davis 2000; Henry 2005; Nondahl 2002). This substantial variance might be explained by the different definitions and criteria of tinnitus that were used and the different populations that were investigated. The largest single study was undertaken in the UK by the Medical Research Council Institute of Hearing Research and was published in 2000 (Davis 2000). This longitudinal study of hearing questioned 48,313 people; 10.1% described tinnitus arising spontaneously and lasting for five or more minutes at a time and 5% described it as moderately or severely annoying. However, only 0.5% reported tinnitus having a severe effect on their life. This is another of the paradoxes of tinnitus: the symptom is very common but the majority of people who experience it are not particularly concerned by it. These figures from the UK are broadly consistent with data collected by the American Tinnitus Association (ATA) which suggests that tinnitus may be experienced by around 50 mil-

lion Americans, or 17% of the US population (ATA 2004). Data also exist for Japan, Europe and Australia (Sindhusake 2003), and estimates suggest that tinnitus affects a similar percentage of these populations, with 1% to 2% experiencing debilitating tinnitus (Seidman 1998). Tinnitus can occur at any age, but the prevalence increases with advancing age (peak prevalence between 40 and 70 years) (Baguley 1999; Crummer 2004; Davis 2000; Hegarthy 2000; Henry 2005; Schleuning 1991). The Oregon Tinnitus Data Archive (Oregon 1995) contains data on the characteristics of tinnitus drawn from a sample of 1630 tinnitus patients. The age groups with the greater prevalence are those between 40 and 49 years (23.9%) and between 50 and 59 years (25.6%).

Diagnosis

Firstly a patient with tinnitus may undergo a basic clinical assessment. This will include the relevant otological, general and family history, and an examination focusing on the ears, teeth and neck and scalp musculature. Referral to a specialist is likely to involve a variety of other investigations including audiological tests and radiology. Persistent, unilateral tinnitus may be due to a specific disorder of the auditory pathway and imaging of the cerebello-pontine angle is important to exclude, for example, a vestibular schwannoma (acoustic neuroma) - a rare benign tumour of the cochleo-vestibular nerve. Other lesions, such as glomus tumours, meningiomas, adenomas, vascular lesions or neuro-vascular conflicts may also be detected by imaging (Marx 1999; Weissman 2000).

Treatment

At present no specific therapy for tinnitus is acknowledged to be satisfactory in all patients. Many patients who complain of tinnitus, and also have a significant hearing impairment, may benefit from a hearing aid (Del Bo 2007). Not only will this help their hearing disability but the severity of their tinnitus may be reduced by masking it through the amplification of ambient sounds. Tinnitus masking can also be achieved with devices which produce a sound that can reduce or eliminate the perception of tinnitus (Hobson 2010).

The role of pharmacotherapy in the treatment of tinnitus is still inconclusive. A wide range of drugs have been proposed for the treatment of tinnitus symptoms since it was shown that intravenous lignocaine may be effective in suppressing tinnitus in some patients (Melding 1978). Pharmacological interventions used include cortisone (Koester 2004), vasodilators, benzodiazepines, lidocaine and spasmolytic drugs. Antidepressants are commonly prescribed for tinnitus. However, two reviews (Baldo 2006; Robinson 2007) have shown that there is no indication that tricyclic antidepressants have a beneficial effect. A Cochrane Review showed that there is no evidence that Ginkgo biloba is effective (Hilton 2004).

Psychological therapies (counselling, cognitive behavioral therapy (CBT) and tinnitus retraining therapy (TRT)) may diminish tin-

nitus by lessening the distress caused by it or by improving quality of life by teaching coping strategies, relaxation techniques and distraction skills (Andersson 1999; Martinez 2010; Phillips 2010). A Cochrane Review has shown that CBT can have an effect on the qualitative aspects of tinnitus and can improve patients' ability to manage the condition (Martinez 2010).

Other options for the management of patients with tinnitus which have been evaluated, include music therapy (Argstatter 2008), traditional Chinese medicine, including acupuncture (Li 2009) and hyperbaric oxygen therapy (HBOT). Hyperbaric oxygen therapy (HBOT) can improve oxygen supply to the inner ear which, it is suggested, may result in an improvement in tinnitus, however a Cochrane Review found insufficient evidence to support this (Bennett 2007).

Different treatment modalities, working on the assumption that tinnitus is related to central auditory hyperactivity, are being evaluated, including transcranial magnetic stimulation (Meng 2009) and extradural electrical stimulation of the auditory cortex (De Ridder 2007).

Anticonvulsants

Anticonvulsants form an important group of drugs used in the treatment of tinnitus, again because of the assumption that tinnitus is related to central auditory hyperactivity. Several different reviews and non-randomised controlled trials have been published which mention anticonvulsants (Dobie 1999; Goodey 1981; Melding 1979; Shea 1978; Waddell 2005). Anticonvulsants might diminish this hyperactivity and treat tinnitus in three ways:

1. they may enhance inhibition in the central auditory system by augmenting the action of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter;
2. they may lower the excitation level in the central auditory system by lessening glutamate transmission, an excitatory neurotransmitter;
3. they may halt the depolarisation of cells, and thus central activation, by blocking voltage-dependent sodium channels.

The effectiveness of anticonvulsants in tinnitus patients is, however, not yet clear. A comprehensive systematic review and meta-analysis of randomised controlled trials evaluating the effectiveness of anticonvulsants in patients with chronic tinnitus is therefore warranted.

OBJECTIVES

To assess the effectiveness of anticonvulsants in patients with chronic tinnitus.

METHODS

Criteria for considering studies for this review

Types of studies

We considered all randomised controlled trials and cross-over trials (if data could be extracted before the cross-over) in which anticonvulsants were compared with placebo, for inclusion in this review. Desirable time points of outcome assessment were four and eight weeks. We excluded single-dose studies.

Types of participants

Patients with chronic tinnitus.

We excluded studies on patients with somatosounds (carotid pathology, arteriovenous malformations, high cardiac output, hypertension, aortic murmurs, vascular tumours, atherosclerosis of the subclavian artery, persistent stapedial artery, turbulent stream in the jugular vein, pseudotumour cerebri or myoclonus of the muscles in the palate or within the ear) and patients with auditory hallucinations. Somatosounds were differentiated on the basis of brain imaging or on characteristic features in the patient's history.

Types of interventions

We included studies using orally administered anticonvulsants (without restrictions regarding type of anticonvulsant, dose or frequency) versus placebo.

Types of outcome measures

Primary outcome

- Improvement in tinnitus-specific health-related quality of life measured with validated questionnaires, such as the Tinnitus Questionnaire (TQ), Tinnitus Handicap Inventory (THI), Tinnitus Handicap Questionnaire (THQ) or Tinnitus Experience Questionnaire (TEQ).

Secondary outcomes

- Improvement in self-assessment of tinnitus severity measured with self-assessment scores.
- Improvement in accompanying symptoms, such as depression, anxiety or sleeping problems measured with validated questionnaires such as the Profile of Mood States, Beck Depression Scale, State-Trait Anxiety Inventory or Brief Symptom Inventory.
- Adverse drug effects.

Search methods for identification of studies

We conducted systematic searches for randomised controlled trials on the effectiveness of anticonvulsants in patients with tinnitus. There were no language, publication year or publication status restrictions. The date of the last search was 26 May 2010.

Electronic searches

We searched the following databases from their inception: the Cochrane Ear, Nose and Throat Disorders Group Trials Register; the Cochrane Central Register of Controlled Trials (CENTRAL) (*The Cochrane Library* 2010, Issue 2); PubMed (1950 onwards); EMBASE (1974 onwards); CINAHL (1982 onwards); PsycINFO; LILACS; KoreaMed; IndMed; PakMediNet; CNKI; MEMR (Index Medicus for WHO Eastern Mediterranean Region); IMSEAR (Index Medicus for WHO South-East Asia Region); Hellis Metasearch; J-East (Science Links Japan); UKCRN (the UK Clinical Research Network Portfolio Database); ICTRP (the World Health Organization International Clinical Trials Registry Platform); ClinicalStudyResults.org; mRCT (the metaRegister of Controlled Trials) and Google.

Search strategies

Subject strategies for databases were modelled on the search strategy designed for CENTRAL (see [Appendix 1](#)). Where appropriate, we combined subject strategies with adaptations of the highly sensitive search strategy designed by the Cochrane Collaboration for identifying randomised controlled trials and controlled clinical trials (as described in the *Cochrane Handbook for Systematic Reviews of Interventions* Version 5.0.1, Box 6.4.b. ([Handbook 2008](#))).

Searching other resources

We checked the reference lists of identified publications for additional trials. We searched PubMed, TRIPdatabase, NLH ENT & Audiology Specialist Library and Google to retrieve existing systematic reviews possibly relevant to this systematic review, so that we could scan their reference lists for additional trials. We sought abstracts from conference proceedings via the Cochrane Ear, Nose and Throat Disorders Group Trials Register and CENTRAL.

Data collection and analysis

We conducted the review according to the recommendations of the *Cochrane Handbook for Systematic Reviews of Interventions 5.0.1* ([Handbook 2008](#)).

Selection of studies

Two review authors (CELH and SPR) scanned the retrieved abstracts to identify relevant randomised controlled trials. The same two authors reviewed the full texts of these articles. We assessed the eligibility of the trials independently. We resolved any differences in opinion by discussion.

Data extraction and management

Three authors (CELH, SPR and MMR) independently collected and extracted data. Disagreement was resolved by discussion. We extracted the following data from each study: number of included patients, inclusion and exclusion criteria, intervention and placebo information, trial duration, primary and secondary outcomes, follow up and adverse events. We contacted the original authors for clarification and further data if trial reports were unclear. Where necessary we arranged translations of papers.

Assessment of risk of bias in included studies

We assessed the quality of the included studies using the Cochrane Collaboration's tool for assessing risk of bias ('Risk of bias' table, *Cochrane Handbook for Systematic Reviews of Interventions*, chapter 8 (Handbook 2008, version 5.0.1). We addressed six specific domains, i.e. sequence generation, allocation concealment, blinding, incomplete outcome data, selective outcome reporting and 'other biases'. By answering pre-specified questions we judged the risk of bias for each domain as 'yes' (low risk of bias), 'no' (high risk of bias) or 'unclear'. We resolved disagreement by discussion (CELH, SPR and MMR). We planned to assess publication bias with a scatter plot (funnel plot) of the log rate ratios (x-axis) versus precision defined as 1/standard error (y-axis) (Handbook 2008).

Assessment of heterogeneity

If heterogeneity was low ($I^2 < 25\%$) we calculated the summary weighted risk differences and 95% confidence intervals (CIs) (random-effects model) by the Mantel-Haenszel method, which weighs studies by the number of events in the control group, using the Cochrane statistical package in Review Manager (RevMan) (version 5.1) (RevMan 2011).

Data synthesis

We used RevMan 5.1 to carry out the meta-analyses for comparable trials and outcomes. For continuous outcomes (questionnaire scores) we calculated standardised mean differences (SMD) and their corresponding 95% confidence intervals (CI). We calculated standardised mean differences by dividing the difference between means by the standard deviation. For dichotomous outcomes, we measured the estimates of effect as risk differences (RD) with their

corresponding 95% confidence intervals. We calculated risk differences using: (proportion of patients with improvement in intervention group) - (proportion of patients with improvement in placebo group). Furthermore, we also planned to perform sensitivity analyses excluding the studies with the lowest methodological quality, according to the Cochrane Collaboration's risk of bias assessment, to establish whether this factor influences the final outcome. We also intended to perform subgroup analyses for cause of tinnitus, duration of tinnitus, patient age, type of anticonvulsant used and outcome measures used. Ultimately it was not possible to perform sensitivity and subgroup analysis, mainly because of lack of data concerning these factors in the original articles.

RESULTS

Description of studies

See: [Characteristics of included studies](#); [Characteristics of excluded studies](#).

Results of the search

We found 96 studies through the combined searches. First, we sifted the articles by title/abstract, leaving 15 articles to read in full text. We excluded eight publications from the review: five articles (Bauer 2006; Guth 1990; Marks 1981; Menkes 1998; Shulman 2008) did not fit the criteria for this review (no anticonvulsant, non-RCT, comments) and three articles (Castagno 1989; Halmos 1982; Viada 1981) were not available through the databases that we used or through the internet. We identified no additional trials by checking the bibliographies of the selected trials.

Included studies

We included seven trials (453 patients) that looked at the effectiveness of anticonvulsants in patients with tinnitus in this review (Bakhshae 2007; Donaldson 1981; Hulshof 1985; Hulshof 1986; Piccirillo 2007; Simpson 1999; Witsell 2006).

Design

Five trials had a randomised controlled trial design (Bakhshae 2007; Hulshof 1985; Hulshof 1986; Piccirillo 2007; Witsell 2006). The other two studies were cross-over trials (Donaldson 1981; Simpson 1999).

Sample size

The average sample size was 62 patients (range 9 to 135 patients).

Settings

Some studies did not describe their settings (Bakhshae 2007; Hulshof 1985; Piccirillo 2007). The other studies described their settings only broadly. Two studies were performed in a tinnitus clinic population (Donaldson 1981; Simpson 1999). One study included patients from a regular otorhinolaryngology practice and also through public advertisement (Witsell 2006). Another study mentioned only that outpatients were included (Hulshof 1986).

Participants

Participant characteristics and inclusion and exclusion criteria were not reported in great detail in most studies. Four studies mentioned the age groups that were included, ranging from 18 to 81 years (Bakhshae 2007; Piccirillo 2007; Simpson 1999; Witsell 2006). Four studies gave information on the duration of the tinnitus. Three studies included patients with tinnitus present at the same level at enrolment for more than the preceding six months (Bakhshae 2007; Piccirillo 2007; Simpson 1999) and one study included patients with tinnitus for more than three months (Witsell 2006). One study described the character of the tinnitus, which needed to be continuous and non-pulsatile (Bakhshae 2007). Five studies applied restrictions on the degree of tinnitus. Three studies used a broad description as “annoying tinnitus” (Hulshof 1985; Hulshof 1986) or “sufficient severity to disrupt daily activities” (Piccirillo 2007). Two studies used a minimal score on a questionnaire or visual analogue scale; ≥ 38 on the THI (Piccirillo 2007), > 30 on the TQ (Bakhshae 2007) or ≥ 5 on a visual analogue scale (VAS) of 0 to 10 (Simpson 1999).

The exclusion criteria most often mentioned were related to the anticonvulsants used (Bakhshae 2007; Piccirillo 2007; Simpson 1999; Witsell 2006). Two studies restricted patients on their hearing level. One included only patients with a sensorineural hearing loss but patients with deafness were excluded (a definition for deafness was not given) (Donaldson 1981). The other study did not include patients with Ménière’s disease, conductive hearing loss, sensorineural hearing loss of “well-known aetiology”, or more than moderately severe loss (> 50 (no units given)) in at least one frequency (Bakhshae 2007). The exclusion criterion “sensorineural hearing loss of well-known etiology” includes noise-induced hearing loss, but is not explained any further. Three studies excluded participants with cognitive disorders or impairment (Bakhshae 2007; Piccirillo 2007; Witsell 2006).

Baseline patient characteristics were often not reported, precluding any judgements about the comparability of the patient groups both within and between trials.

Interventions

These studies investigated four different anticonvulsants. Gabapentin was the drug of investigation in three trials in different dosages and duration (four weeks 900 mg per day; four weeks 1800 mg per day; eight weeks 3600 mg per day) (Bakhshae 2007; Piccirillo 2007; Witsell 2006). Two studies looked at carbamazepine in different dosages and durations (eight weeks 200 mg; four weeks 450 mg) (Donaldson 1981; Hulshof 1985). Lamotrigine and flunarizine were both studied in one trial (Hulshof 1986; Simpson 1999). All studies were placebo-controlled.

None of the studies included another form of treatment during the study period (such as counselling, for example). All studies had one or more evaluation time points. None of the studies described in detail how or by whom the evaluation was performed and if there was any form of interaction between the clinician and the patients during the study.

Outcomes

Three studies used a validated questionnaire as outcome measurement (our primary outcome measure); the Tinnitus Handicap Inventory (THI) was used in two trials (Piccirillo 2007; Witsell 2006) and the Tinnitus Questionnaire (TQ) in one (Bakhshae 2007). Four studies used different Likert scales as outcome measurement (our secondary outcome measure) (Donaldson 1981; Hulshof 1985; Hulshof 1986; Simpson 1999).

See: [Characteristics of included studies](#); [Characteristics of excluded studies](#).

Risk of bias in included studies

Figure 1 and Figure 2 show the results of the risk of bias assessment according to the Cochrane Collaboration’s tool for assessing risk of bias. Figure 1 shows the judgements about each methodological quality item presented as percentages across included studies, whereas Figure 2 shows the judgement for each included study separately. Detailed information about the assessment can be found in the [Characteristics of included studies](#).

Figure 1. 'Risk of bias' graph: review authors' judgements about each methodological quality item presented as percentages across all included studies.

Figure 2. 'Risk of bias' summary: review authors' judgements about each methodological quality item for each included study.

	Random sequence generation (selection bias)	Allocation concealment (selection bias)	Blinding (performance bias and detection bias)	Incomplete outcome data (attrition bias)	Selective reporting (reporting bias)	Other bias

Bakhshae 2007 (*gabapentin*): this appears to be a cross-over trial for which the randomisation procedure and treatment protocol are not described clearly. It therefore scored low for sequence generation, allocation concealment and blinding. The drop-out rate was high (59%) and these incomplete outcome data are not addressed. Tinnitus patients with a sensorineural hearing loss of well-known aetiology were excluded. This exclusion criterion is not described sufficiently, but it is stated to include noise-induced hearing loss. As this is one of the main causes of hearing loss, and consequently tinnitus, this will decrease the generalisability of this study.

Donaldson 1981 (*carbamazepine*): this appears to be a single-blind trial and therefore scored low for blinding. The drop-out rate is high (21%) and these incomplete outcome data are not addressed. The other items were not reported clearly in the paper.

Hulshof 1985 (*carbamazepine*): the drop-out rate in the intervention group is high (41%) and these incomplete data are not addressed. The other items were not reported clearly in the paper.

Hulshof 1986 (*flunarizine*): due to incomplete reporting none of the items to assess the risk of bias could be scored.

Piccirillo 2007 (*gabapentin*): all items were reported and methodologically sound (i.e. low risk of bias).

Simpson 1999 (*lamotrigine*): blinding appears to have been carried out correctly as identical capsules were used for placebo. The other items were not adequately reported and therefore could not be assessed.

Witsell 2006 (*gabapentin*): the randomisation process, allocation concealment and blinding are all reported and methodologically sound (i.e. low risk of bias for these domains). The drop-out rate was high (30%), however, and selective loss to follow up cannot be precluded.

In summary, the overall risk of bias of the included studies is 'high' or 'unclear'.

Effects of interventions

Improvement in tinnitus-specific health-related quality of life

The studies included in this review did not show a positive effect of anticonvulsants on the primary outcome. Only three studies, all of gabapentin, evaluated the effect through a validated questionnaire (**Bakhshae 2007**; **Piccirillo 2007**; **Witsell 2006**). One study showed a negative effect of gabapentin, one study showed a small, statistically non-significant, positive effect and the third study showed no difference between gabapentin and placebo. When the

data of the first two studies are pooled (**Witsell** could not be included because of lack of exact numbers) no effect of gabapentin is found (standardised mean difference (SMD) 0.07, 95% confidence interval (CI) -0.26 to 0.40).

Bakhshae 2007 showed that treatment with gabapentin for four weeks at 900 mg/d resulted in a negative effect of gabapentin compared to placebo with an increase in Tinnitus Questionnaire (TQ) score of 18.4 points (standardised mean difference (SMD) 0.82, 95% CI 0.07 to 1.58). This standard mean difference is low because of high standard deviations (20.22 and 23.36, with a total possible score of 84). **Piccirillo 2007** showed that treatment with gabapentin for eight weeks at 900 to 3600 mg/d resulted in a positive, non-significant effect for gabapentin with a difference compared to placebo of 2.4 points on the Tinnitus Handicap Inventory (THI) (SMD -0.11, 95% CI -0.48 to 0.25). The data in this study also included high standard deviations (23.52 and 19.02, with a total possible score of 100). In a subgroup of patients with normal hearing the THI improved significantly more in the gabapentin group than in the placebo group (difference 17.2 points, SMD 0.89, 95% CI -1.27 to -0.50). **Witsell 2006** showed no differences on the THI after a four-week treatment with gabapentin up to 1800 mg compared to placebo (exact numbers could not be extracted from the article).

Improvement in self-assessment of tinnitus severity

The patient's self-assessment of their tinnitus, our secondary outcome, was included in all studies as an outcome measurement. Five out of six studies did not show a positive effect of anticonvulsants (**Bakhshae 2007**; **Donaldson 1981**; **Hulshof 1986**; **Piccirillo 2007**; **Simpson 1999**; **Witsell 2006**). When these data are pooled in a meta-analysis, however, this shows a small favourable effect of anticonvulsants (risk difference (RD) 14%, 95% CI 6% to 22%). This meta-analysis includes all levels of improvement on the various Likert scale, and therefore these patients may still be annoyed to some or a large degree by their tinnitus. It can be presumed that the best possible scores on these Likert scales (complete effect, abolition, not annoying, not annoying/disappeared, very much better, much better) entail annulment of annoyance. Summarised as near or total eradication of tinnitus annoyance, a meta-analysis of these results showed no effect of anticonvulsants (RD 4%, 95% CI -2% to 11%) (**Bakhshae 2007**; **Donaldson 1981**; **Hulshof 1985**; **Hulshof 1986**; **Piccirillo 2007**; **Simpson 1999**). **Figure 3** and **Figure 4** show the results of these meta-analyses.

Figure 3. Forest plot of comparison: I Self-assessment, outcome: I.1 Any positive effect.

Figure 4. Forest plot of comparison: I Self-assessment, outcome: I.2 near or total eradication of tinnitus annoyance

Gabapentin

Bakhshae 2007 showed no effect of gabapentin on a self-assessment score (RD 5%, 95% CI -40% to 30%). Complete response was achieved on this score in 13% in the gabapentin group and in 14% of the placebo group (RD 2%, 95% CI -26% to 23%).

Piccirillo 2007 reported a non-significant improvement in 19% in the gabapentin group compared to 9% in the placebo group (RD 10%, 95% CI -2% to 22%) on a self-assessment score. A large result was achieved in 2% in the gabapentin group and not in the placebo group (RD 2%, 95% CI -3% to 6%). This difference is also not significant.

Witsell 2006 found a significant effect for gabapentin using a self-assessment score: 38% of patients in the gabapentin group reported a positive effect compared to 7% of placebo patients (RD 30%, 95% CI 14% to 48%).

Carbamazepine

Donaldson 1981 showed that treatment with carbamazepine 200 mg twice a day for two months resulted in a non-significant positive effect in 45% as compared to 21% in the placebo group on a self-assessment score (RD 10%, 95% CI -8% to 27%). A good or excellent result was achieved in 38% in the carbamazepine group and in 20% of the placebo group (RD 18%, 95% CI -2% to 39%).

Hulshof 1985 showed that treatment with carbamazepine 150 mg three times a day for 30 days resulted in a non-significant negative effect: in 8% as compared to 13% in the placebo group on a self-assessment score (RD -4%, 95% CI -21% to 13%).

Flunarizine

Hulshof 1986 showed that treatment with 10 mg flunarizine for six weeks resulted in a non-significant improvement of tinnitus in 44% as compared to 24% in the placebo group using a self-

assessment score (RD 20%, 95% CI -6% to 46%). Disappearance of the annoyance of tinnitus was non-significantly lower in the flunarizine group; 16% in the flunarizine group compared to 20% in the placebo group (RD -4%, 95% CI -25% to 17%)

Lamotrigine

Simpson 1999 showed that treatment with lamotrigine up to 100 mg for eight weeks resulted in a non-significant improvement in tinnitus in 36% as compared to 19% in the placebo group using a self-assessment score (RD 16%, 95% CI -6% to 38%). A large improvement was found in 10% of the lamotrigine group and not found in placebo group (RD 10%, 95% CI -2% to 21%). This difference is also not significant.

Improvement in accompanying symptoms (e.g. depression, anxiety or sleeping problems)

Only two studies included outcome measurements on accompanying symptoms. Witsell et al did not find a significant difference in the total mood score of the Profile of Mood States (exact numbers could not be extracted from the article) between the gabapentin and the placebo group (Witsell 2006). Piccirillo et al included the Beck Depression Scale and Brief Symptom Inventory in their analysis, but did not include a description of these data in their article (Piccirillo 2007).

Adverse drug effects

In all studies side effects were reported. Fifty-two of the 286 patients (18%) that received an anticonvulsant experienced side effects. Nausea (12 patients) and dizziness (11 patients) were the most frequently reported. Other side effects reported were: headache (five patients), elevated tiredness (four patients), vomiting during the treatment (three patients), weight gain (two patients), sleep disturbance (two patients), and diarrhoea, mouth sores and decreased libido (one patient). In 14 patients the side effects were not specified.

DISCUSSION

Summary of main results

This review of seven trials (453 patients) shows that current evidence regarding the effectiveness of anticonvulsants has a significant risk of bias. Nevertheless, based on the findings in this review anticonvulsants do not show a beneficial effect on tinnitus, measured through validated questionnaires. The seven included trials investigated four different anticonvulsants: gabapentin, carbamazepine, lamotrigine and flunarizine. Of the three studies that measured improvement with a validated questionnaire (our

primary outcome), one study showed a significant negative (adverse) effect of gabapentin compared to placebo with an increase in Tinnitus Questionnaire (TQ) score of 18.4 points (standardised mean difference (SMD) 0.82, 95% confidence interval (CI) 0.07 to 1.58). A second study did not show a significant effect of gabapentin compared to placebo (difference 2.4 points on the Tinnitus Handicap Inventory (THI), SMD -0.11, 95% CI -0.48 to 0.25). When the data from these two studies are pooled no effect of gabapentin is found (SMD 0.07, 95% CI -0.26 to 0.40). A third study comparing gabapentin and placebo did not show a difference using the THI. A meta-analysis of 'any positive effect' (yes versus no) based on a self-assessment score (secondary outcome) showed a small beneficial effect (risk difference (RD) 14%, 95% CI 6% to 22%) for anticonvulsants. However, this effect is not large enough to be considered clinically relevant. It shows that in 14% an improvement can be seen, which is in itself a low number. Secondly, in tinnitus a minor improvement is not always enough to obtain the treatment goal: a decrease in annoyance to a level in which it does not interfere with the patient's quality of life. The treatment goal to be aimed at is near or total eradication of tinnitus annoyance: a meta-analysis of this outcome showed no effect for anticonvulsants (RD 4%, 95% CI -2% to 11%). Side effects of the anticonvulsants used were experienced by 18% of patients.

Overall completeness and applicability of evidence

The results of this review are only applicable to the general tinnitus population. Since tinnitus is a diverse symptom, different subgroups of tinnitus patients may exist, potentially leading to different results for different therapies. Due to the lack of data on factors that could potentially modify the effect of anticonvulsants (such as degree of burden, aetiology of hearing loss, duration of tinnitus or whether the patients actively seek help or not), it was not possible to perform subgroup analyses to identify patients that might benefit from anticonvulsants. Piccirillo et al, however, showed a beneficial effect of gabapentin in a subgroup with normal hearing (Piccirillo 2007). It is thus possible that some subgroups might benefit more than others from treatment with anticonvulsants.

Quality of the evidence

Most of the studies included in this review have a moderate or high risk of bias as descriptions of the methodology used are minimal.

Potential biases in the review process

During the review process we identified potential biases both in the individual trials and in the review process itself.

Since tinnitus is a subjective symptom, no gold standard is available to measure the severity of the symptom. Furthermore, there is as yet no consensus regarding the best way to measure treatment effects, making it difficult to interpret and compare results. Validated tinnitus questionnaires are, however, deemed to be more reliable than other subjective measurements, such as visual analogue scales and Likert scales. Audiometric measurements of tinnitus are not regarded as reliable outcome parameters. We therefore used validated questionnaires as our primary outcome measure. Of the included studies one used the TQ and two the THI as outcome measurement. These are the most commonly used questionnaires, but as mentioned above it remains unclear whether these questionnaires are usable for measuring treatment effects (Kamalski 2010).

Due to the large variety of outcome measures used it was not possible to explore publication bias in a funnel plot.

The authors of this review were not blinded to the authorship and origin of the included studies since we knew most of the literature before embarking on this review.

AUTHORS' CONCLUSIONS

Implications for practice

Current evidence regarding the effectiveness of anticonvulsants in patients with tinnitus has significant risk of bias. There is no evidence from studies performed so far to show that the anticonvulsants studied (gabapentin, carbamazepine, flunarizine and lamotrigine) have a large positive effect in the treatment of tinnitus but a small effect (of doubtful clinical significance) has been demonstrated.

Implications for research

Future trials should be methodologically sound. They should be set up as randomised clinical trials. Patients, treatment providers and outcome assessors should be blinded. Randomisation should be performed in a reliable way (e.g. by computer) and the placebo used should be identical to the actual treatment. Results should be analysed by intention-to-treat.

Consensus should be reached about evaluation methods so that studies can be compared. A first step towards reaching this consensus had been made by the Tinnitus Research Initiative (Langguth 2007). We would recommend following these guidelines on outcome measurements. The two most commonly used validated tinnitus questionnaires are the Tinnitus Questionnaire (TQ) and the Tinnitus Handicap Inventory (THI), so use of at least one of these in evaluations is recommended.

Study populations should be clearly defined in future trials, including degree of burden, aetiology of hearing loss, duration of tinnitus and other tinnitus characteristics, and whether the patients actively seek help or not.

Future trials should have large enough study populations so that possible effects in subgroups can be evaluated. Smaller trials should only be performed in well-chosen subgroups. Decisions on the type of subgroups should be based (if possible) on earlier studies showing a possible (better) result in these subgroups.

CHARACTERISTICS OF STUDIES

Characteristics of included studies [ordered by study ID]

Bakhshae 2007

Methods	Prospective, double-blind, placebo-controlled, cross-over trial	
Participants	<p>30 participants with moderate to severe idiopathic subjective tinnitus 16 gabapentin, 14 placebo</p> <p>Inclusion criteria:</p> <ul style="list-style-type: none"> • 36 to 81 years • continuous non-pulsatile tinnitus • duration at least 6 months • total Tinnitus Questionnaire (TQ) score > 30 <p>Exclusion criteria:</p> <ul style="list-style-type: none"> • active Ménière's disease • signs or symptoms of intracranial disease or vestibular disorder • conductive hearing loss or surgically correctable component • sensorineural hearing loss of well-known aetiology, such as noise-induced hearing loss • totally deaf or more than moderately severe loss (> 50) in at least one frequency • concurrent treatment with centrally-acting medication • diabetes mellitus • related to gabapentin use (impaired renal function, (planned) pregnancy, contraindications to gabapentin, metabolic or endocrine disorder) • mental retardation and severe cognitive disorders 	
Interventions	<p>Intervention: 900 mg gabapentin per day Control: identical placebo (opaque starch-filled gel capsules) Duration: 4 weeks</p>	
Outcomes	<p>Primary outcome: psychoacoustically determined tinnitus loudness and TQ score Secondary outcome: Tinnitus Severity Index score</p>	
Notes	<p>Drawbacks:</p> <ul style="list-style-type: none"> • Exclusion criteria result in an intervention group not representative of the majority of tinnitus patients (patients with sensorineural hearing loss of well-known aetiology such as noise-induced hearing loss are excluded) <p>Adverse events: 3% experienced dizziness</p>	
<i>Risk of bias</i>		
Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	High risk	<p>Quote: "every participant received the same treatment sequence, therefore evaluations could be made with each participant serving as their own control"</p> <p>Quote: "16 participants in the study group</p>

		<p>and 14 in the control group completed the protocol”</p> <p>Comment: this study is described as a RCT and the results show an intervention and a placebo group. The methods section, however, describes every participant receiving the same treatment sequence and serving as their own control. This implies a cross-over design</p> <p>As it is stated clearly that everybody received the same treatment sequence we believe that no randomisation was performed</p>
Allocation concealment (selection bias)	High risk	<p>Quote: “every participant received same treatment sequence”</p> <p>Comment: a fixed sequence excludes the possibility of allocation concealment</p>
Blinding (performance bias and detection bias) All groups	Unclear risk	<p>Quote: “double blind”</p> <p>Quote: “neurontin capsules and placebo were individually enclosed in snap-lock, opaque starch-filled gel capsules by an investigational pharmacist”</p> <p>Quote: “every participant received same treatment sequence”</p> <p>Comment: blinding not adequately described</p> <p>1) Identical pills suggests blinding of patients</p> <p>2) Same treatment sequence makes blinding of study personnel and outcome assessors doubtful</p>
Incomplete outcome data (attrition bias) All outcomes	High risk	<p>Quote: “42 patients were noncompliant with the study instructions and one failed to complete the study due to side effects”</p> <p>Quote: “30 patients completed the protocol”</p> <p>Comment: not adequately described; 59% drop-out is implied (not included in the analysis)</p>
Selective reporting (reporting bias)	Unclear risk	No protocol available
Other bias	Unclear risk	<ul style="list-style-type: none"> • No adequate baseline table to check comparability of groups • Not described if groups were treated equally

Donaldson 1981

Methods	Placebo-controlled, randomised, cross-over trial
Participants	78 tinnitus clinic patients 62 carbamazepine, 62 placebo (patients who dropped out not included) Inclusion criteria: <ul style="list-style-type: none"> • tinnitus • sensorineural hearing loss Exclusion criteria: <ul style="list-style-type: none"> • conductive hearing loss • deafness
Interventions	Intervention: 100 mg carbamazepine twice a day Control: placebo tablets Duration: 2 times 2 months
Outcomes	Patients' assessment of tinnitus change on a percentage (not fully described, presumably 0% to 100%) analogue scale: excellent (abolition); good (> 60% reduction); partial (30% to 60% reduction); no significant relief (< 30% reduction)
Notes	Adverse events: types not described 18% withdrew because of side effects from carbamazepine and 3% withdrew because of side effects from placebo

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Quote: "randomised system" Comment: randomisation process not explained
Allocation concealment (selection bias)	Unclear risk	Comment: no information provided
Blinding (performance bias and detection bias) All groups	High risk	Quote: "double blind system" Comment: blinding is not explained. The study date and the fact that no study pharmacy is mentioned mean that adequate blinding is judged highly unlikely
Incomplete outcome data (attrition bias) All outcomes	High risk	Quote: "14 patients withdrew whilst taking carbamazepine and 2 whilst taking placebo" Comment: 21% drop-out (18% intervention, 3% placebo) is too high and patients that dropped out were excluded from analyses
Selective reporting (reporting bias)	Unclear risk	No protocol available

Donaldson 1981 (Continued)

Other bias	Unclear risk	<ul style="list-style-type: none"> • No adequate baseline table to check comparability of groups • Not described if groups were treated equally
------------	--------------	---

Hulshof 1985

Methods	Double-blind, placebo-controlled, randomised trial
Participants	48 patients with annoying tinnitus 24 carbamazepine, 24 placebo No further inclusion/exclusion criteria described
Interventions	Intervention: 150 mg carbamazepine 3 times a day Control: identical-looking gelatin placebo capsules Duration: 30 days
Outcomes	Likert scale (tinnitus disappeared, tinnitus improved, tinnitus did not disappear)
Notes	Adverse events: 63% of carbamazepine patients experienced side effects (8 dizziness, 8 nausea, 4 headache, 2 tiredness, 2 vomiting, 1 diarrhoea). 4% of placebo patients experienced side effects (1 headache)

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Quote: "randomised controlled trial" Comment: randomisation process not explained
Allocation concealment (selection bias)	Unclear risk	Quote: "after randomisation" Randomisation process not explained
Blinding (performance bias and detection bias) All groups	Unclear risk	Quote: "double-blind controlled trial" Quote: "identical-looking gelatin capsules" Comment: blinding not adequately described <ul style="list-style-type: none"> • Identical pills suggest at least blinding of patients • Measurements of carbamazepine levels in serum makes blinding of personnel doubtful
Incomplete outcome data (attrition bias) All outcomes	High risk	Quote: "10 patients withdrew in carbamazepine group because of side effects" Comment: 42% drop-out in the interven-

Hulshof 1985 (Continued)

		tion group is very high; patients were included in analyses
Selective reporting (reporting bias)	Unclear risk	No protocol available
Other bias	Unclear risk	<ul style="list-style-type: none"> • No adequate baseline table to check comparability of groups • Not described if groups were treated equally

Hulshof 1986

Methods	Double-blind, placebo-controlled, randomised clinical trial	
Participants	50 patients with annoying tinnitus 25 flunarizine, 25 placebo No further inclusion/exclusion criteria described	
Interventions	Intervention: 10 mg flunarizine once a day Control: identical placebo capsules Duration: 6 weeks	
Outcomes	Likert scale (0 tinnitus has disappeared, 1 tinnitus persists but is no longer annoying, 2 tinnitus annoying but less severe, 3 no change, 4 severity increased)	
Notes	Adverse events: 8% of flunarizine patients experienced sleepiness during the day. No side effects were mentioned in the placebo group	

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Quote: "randomisation" Comment: randomisation process not explained
Allocation concealment (selection bias)	Unclear risk	Quote: "randomisation" Comment: randomisation process not explained
Blinding (performance bias and detection bias) All groups	Unclear risk	Quote: "double blind" Comment: blinding process not adequately described <ul style="list-style-type: none"> • Identical pills suggest at least blinding of patients • Measurement of flunarizine levels in serum makes blinding of personnel doubtful

Hulshof 1986 (Continued)

Incomplete outcome data (attrition bias) All outcomes	Unclear risk	Comment: not adequately described if there were no drop-outs, or if the 50 patients analysed were the patients left over after exclusion of a number of drop-outs
Selective reporting (reporting bias)	Unclear risk	No protocol available
Other bias	Unclear risk	<ul style="list-style-type: none"> • No adequate baseline table to check comparability of groups • Not described if groups were treated equally

Piccirillo 2007

Methods	Double-blind, placebo-controlled, randomised trial	
Participants	<p>135 subjects with severe idiopathic subjective tinnitus (1028 screened) 59 gabapentin, 56 placebo</p> <p>Inclusion criteria:</p> <ul style="list-style-type: none"> • 18 to 65 years • duration of 6 months or longer • sufficient severity to disrupt daily activities • Tinnitus Handicap Inventory (THI) \geq 38 <p>Exclusion criteria:</p> <ul style="list-style-type: none"> • presence of a treatable otological disorder related to the tinnitus • organic mental disorder • related to gabapentin use (impaired renal function, previous use of gabapentin) 	
Interventions	<p>Intervention: 3600 mg gabapentin per day in 3 doses or highest possible dose reached (titration: week 1, 900 mg/day; week 2, 1800 mg/day; week 3, 2700 mg/day; week 4, 3600 mg/day)</p> <p>Control: identical blue placebo capsule, similar administration</p> <p>Duration: 4 weeks titration period and 4-week fixed-dose period</p>	
Outcomes	<p>Primary outcome: change in THI from week 0 to 8 between treatment arms</p> <p>Secondary outcomes: 1) Patient Global Impression of Change score, 2) Brief Symptom Inventory, 3) Beck Depression Scale score</p>	
Notes	<p>Drawbacks:</p> <ul style="list-style-type: none"> • Some results difficult to interpret from tables because of different subgroups in baseline and results tables • Unclear why slightly more patients received gabapentin than placebo <p>Adverse events: 7% withdrew because of side effects (3 nausea, 2 weight gain, 2 sleep disturbance, 2 dizziness, 1 seizure). It was not mentioned if the side effects occurred in the gabapentin or the placebo group</p>	

Risk of bias

Piccirillo 2007 (Continued)

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Quote: "sequentially randomised according to a computer-generated random code"
Allocation concealment (selection bias)	Low risk	Quote: "research pharmacist maintained the randomisation schedule"
Blinding (performance bias and detection bias) All groups	Low risk	Quote: "double blind" Quote: "matching placebo capsules", "identical blue capsules"
Incomplete outcome data (attrition bias) All outcomes	Low risk	16% drop out in gabapentin group and 14% in placebo group Modified intention-to-treat analyses (inclusion of patients with at least 1 dose of study medication and at least 1 follow-up assessment)
Selective reporting (reporting bias)	Unclear risk	No protocol available
Other bias	Low risk	-

Simpson 1999

Methods	Double-blind, placebo-controlled, cross-over trial
Participants	33 subjects from a general tinnitus clinic population No other inclusion criteria mentioned Exclusion criteria <ul style="list-style-type: none"> • younger than 18 or older than 75 years • related to lamotrigine use (pregnancy, (history of) treatment for epilepsy or treatment with antiepileptic drugs, history of gastrointestinal hepatic or renal insufficiency) • < 5 on visual analogue scale (VAS) of 1 to 10 for "annoyance" • tinnitus at present level for less than 6 months
Interventions	Intervention: 100 mg/d lamotrigine (titration: week 1 to 2, 25 mg/day; week 3 to 4, 50 mg/day) Control: matching placebo tablets Duration: 4 weeks titration period, 4 weeks fixed-dose period, followed by same regimen after cross-over
Outcomes	Questionnaires (Likert: much better, better, no change, worse, much worse), visual analogue scales (loudness, annoyance, awareness) and audiological measurements (pure tone audiometry, masking audiogram, pitch matching of tinnitus, loudness matching of tinnitus, masking of tinnitus, residual inhibition and uncomfortable loudness levels) at 0 weeks, 4 weeks, 8 weeks, 12 weeks and 16 weeks

Simpson 1999 (Continued)

Notes	<p>Drawbacks:</p> <ul style="list-style-type: none"> • No primary outcome measurement or time point stated • No wash-out period <p>Adverse events: 3% of patients withdrew in the lamotrigine group (1 nausea, vomiting and headache) and 3% of patients withdrew in the placebo group (1 dizziness and rash)</p>
-------	---

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	Quote: "randomly allocated" Comment: randomisation process not explained
Allocation concealment (selection bias)	Unclear risk	Randomisation process not explained
Blinding (performance bias and detection bias) All groups	Unclear risk	Quote: "double-blind" Quote: "matching placebo tablets" Comment: blinding process not adequately described. Identical pills suggest at least blinding of patients
Incomplete outcome data (attrition bias) All outcomes	Low risk	6% drop-out, evenly distributed in placebo and lamotrigine group Left out from results
Selective reporting (reporting bias)	Unclear risk	No protocol available No primary outcome measurement or time point stated
Other bias	Unclear risk	<ul style="list-style-type: none"> • No adequate baseline table to check comparability of groups • Not described if groups were treated equally

Witsell 2006

Methods	Double-blind, placebo-controlled, randomised clinical trial
Participants	<p>79 patients with moderate tinnitus (102 screened) 53 gabapentin, 26 placebo</p> <p>Inclusion criteria:</p> <ul style="list-style-type: none"> • 18 to 70 years • chief complaint of tinnitus > 3 months • understands English and has a telephone <p>Exclusion criteria:</p> <ul style="list-style-type: none"> • related to gabapentin use (allergic to gabapentin, history of chronic renal failure,

	pancreatitis, hypotension, seizure disorder, past use of gabapentin, pregnant or breast feeding) <ul style="list-style-type: none"> • cognitive impairment 	
Interventions	Intervention: 1800 mg gabapentin per day in 3 doses Control: identical placebo capsules in same dosing schedule Duration: 2 week escalating-dose period (week 1, 300 mg/day; week 2, 900 mg/day), 2 week fixed-dose period, 2 weeks descending-dose period (week 5, 900 mg/day; week 6, 300 mg/day)	
Outcomes	Primary outcome: Tinnitus Handicap Inventory (THI), no time period stated (questionnaire was administered at week 1, week 4, week 10) Secondary outcome: Profile of Mood States (POMS)	
Notes	Adverse events: 2% of patients in the gabapentin group experienced side effects (1 mouth sores and decreased libido)	
Risk of bias		
Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Quote: "computerised random-number generator"
Allocation concealment (selection bias)	Low risk	Quote: "key to randomisation was held by the pharmacy"
Blinding (performance bias and detection bias) All groups	Low risk	Quote: "placebo identical to the gabapentin capsules"
Incomplete outcome data (attrition bias) All outcomes	High risk	30% drop-out, selective loss to follow up Unclear handling of drop-out
Selective reporting (reporting bias)	Unclear risk	No protocol available
Other bias	Unclear risk	<ul style="list-style-type: none"> • No adequate baseline table to check comparability of groups • Not described if groups were treated equally

RCT: randomised controlled trial

Characteristics of excluded studies *[ordered by study ID]*

Study	Reason for exclusion
Bauer 2006	ALLOCATION Not randomised (cross-over trial with a set regiment)
Castagno 1989	Not available
Guth 1990	ALLOCATION Random; randomisation process not explained Cross-over design PARTICIPANTS 66 patients (66 AOAA, 66 placebo) Inclusion criteria: <ul style="list-style-type: none"> • severe tinnitus Exclusion criteria: <ul style="list-style-type: none"> • women with child-bearing potential • hepatic, cardiac, gastrointestinal or convulsive disorders • mental incompetence INTERVENTIONS Intervention: Amino-oxyacetic acid (AOAA) is not a registered anticonvulsant
Halmos 1982	Not available
Marks 1981	ALLOCATION Not described PARTICIPANTS 9 patients Inclusion criteria: <ul style="list-style-type: none"> • constant and unilateral tinnitus • more than trivial tinnitus • virtually normal hearing • easily reproducible tinnitus matching INTERVENTIONS Intervention: single dose of 200 mg carbamazepine
Menkes 1998	ALLOCATION Article is a letter to the editor and not a randomised controlled trial
Shulman 2008	ALLOCATION Article is a comment and not a randomised controlled trial
Viada 1981	Not available

DATA AND ANALYSES

Comparison 1. Self-assessment

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
1 Any positive effect	6	445	Risk Difference (M-H, Fixed, 95% CI)	0.14 [0.06, 0.22]
2 Near or total eradication of tinnitus annoyance	6	379	Risk Difference (M-H, Fixed, 95% CI)	0.04 [-0.02, 0.11]

Comparison 2. Questionnaires

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
1 Tinnitus Handicap Inventory (THI)	1	115	Std. Mean Difference (IV, Fixed, 95% CI)	-0.11 [-0.48, 0.25]
2 Tinnitus Questionnaire (TQ)	2	145	Std. Mean Difference (IV, Fixed, 95% CI)	0.07 [-0.26, 0.40]
