leads to deactivation of the system. GPA analysis of the polymer indicated $M_n$ and $M_w$ values of 21,000 and 47,900 daltons (Da), respectively, and a DSC curve for the polymer exhibited no detectable exotherm prior to the onset of crystalline melting at 131.6 °C. In contrast, the reactions of (Ph$_3$SiO)$_3$VO and (n-Pro$_2$O)$_2$VO under identical conditions gave no polyethylene; the only observable reaction (by $^{13}$C NMR) was the metathesis of alkyl ligands on Al for alkoxide ligands on V. 5,6 We have not extensively explored the use of other cocatalysts with 2, but we have observed similar activities with Et$_2$Al and somewhat lower activities with (Me$_3$SiCH$_2$)$_3$AI.

A survey of the catalyst's reactivity indicates that other olefins can also be polymerized or copolymerized, although not as efficiently as ethylene. For example, the reaction of 2 and Me$_3$Al (3 equiv) in propylene (25 °C, ~8 atm, 3 h) gave small amounts (~125 turnovers) of atactic polypolypropylene (MW < 10,000). Similarly, the copolymerization of ethylene (1%) in neat propylene produced small amounts (~350 turnovers) of copolymer, which contained 5–10% propylene (by $^{13}$C NMR). 9 One olefin that is polymerized well by our catalyst is 1,3-butadiene; an ampple containing 50 mL of neat butadiene (bp ~4–5 °C) completely solidifies within 30 min to create a partial vacuum inside the ampule. $^1$H and $^{13}$C NMR spectroscopy 10 indicated that the resulting product was >95% trans-1,4-polybutadiene. 11

The activity of the catalyst is sensitive to the amount of Me$_3$Al used. As shown in Figure 1, polyethylene production (1 atm, 25 °C, 3 h) is maximized when approximately 3 equiv of Me$_3$Al is used. Large excesses of Me$_3$Al lead to deactivation of the catalyst. Both observations are contrary to the behavior of typical “soluble catalysts” 12 prepared from trialkylvanadates, which typically require large excesses of alkylaluminum reagents (15–500 equiv) to initiate olefin polymerization. 13 In light of the narrow polydispersity measured for our polyethylene sample (2.28), these results suggest that a well-defined catalyst is being formed 14 and that this catalyst is fundamentally different from these conventional soluble V catalysts.

The presence and equilibration of both 2 and 3 in the starting solution greatly complicate mechanistic studies, but several polymerization reactions performed at -30 °C, where the equilibration of 2 and 3 is negligibly slow, indicate that the active catalyst is derived from the reaction of 2 with Me$_3$Al. Specifically, the addition of Me$_3$Al to an ethylene-saturated solution of 2 and 3 (~10:90 by $^{51}$V NMR) at ~30 °C initiates ethylene polymerization by slowly consuming 2, but does not affect the amount of 3 in solution. Furthermore, ethylene polymerization is only initiated when the $^{51}$V NMR resonance for 2 is initially present. The active polymerization catalyst(s) in our system is (are) currently not known, and it would be inappropriate to speculate about its identity without additional data. 15

It is important to note that this POMSS-based catalyst is capable of polymerizing olefins when stoichiometrically similar complexes (e.g., (Ph$_3$SiO)$_3$VO and (n-Pro$_2$O)$_2$VO) show little or no activity. Since our understanding of surface catalysis is both based upon and inherently limited by known reaction chemistry of solution complexes, the unique chemistry of V-containing POMSS may provide new insights into the chemistry of silica-supported vanadium catalysts. Efforts to elucidate the active polymerization catalyst(s) in this interesting system are currently in progress.

Geodesic structures were developed by R. Buckminster Fuller on the basis of his insight into their structural economy and stability. In 1985, similar considerations led Smalley, Kroto, et al. 10 to propose that $C_{60}$, observed in carbon cluster beam experiments, 14 possessed the geometry of a soccer ball, and they named it "Buckminsterfullerene." Their prediction of the stability of this molecule, as well as other fullerenes, has been stunningly verified by the recent synthesis of macroscopic amounts of $C_{60}$ and $C_{70}$. 1-5 This development has sparked intense research activity in the production and characterization of these materials. 6-8 Raman 9

equivalent. The resonance position for \( \text{C}_6 \) is in excellent accord with similar carbons\(^{19} \) in azulene (140.2 ppm), fluorene (141.6 ppm) and 3,5,8-trimethylacehtylen, showing that all carbons in the molecule are chemically equivalent. The connectivity obtained is linear and highlighted by lines; the asymmetrical intensity string for the two resonances of a bonded carbon pair. The connectivity obtained is consistent with the soccer ball structure for \( \text{C}_{60} \) (Figure 1).

In this communication we show that it is possible to map the bonding connectivities of \( \text{C}_{70} \) and obtain definitive resonance assignments by the 2D INADEQUATE NMR experiment.\(^{22-25} \) This experiment correlates the \( ^{13} \text{C} \) NMR line of a carbon to that of its bonded neighbor by excitation of a shared double quantum coherency via scalar \( J \) coupling, thus yielding the carbon connectivity map of the molecule. \( \text{C}_{60} \) samples enriched to \( \approx 20\% \) \( ^{13} \text{C} \) were used to increase the probability of adjacent \( ^{13} \text{C} \) atoms, resolving the data acquisition time at the resonance frequencies by about two orders of magnitude. The enriched clusters were prepared by using cored carbon rods loaded with amorphous \( ^{13} \text{C} \) powder (Cambridge Isotopes) in an arc fullerene generator.\(^{6,12,26} \)

The 2D NMR spectrum of \( \text{C}_{70} \) is shown in Figure 1. For this experiment, two bonded carbons share a double quantum frequency in the vertical dimension, and peaks occur at the two respective chemical shifts in the horizontal dimension, allowing the correlation to be made. In addition, each peak will be split into a doublet by the relevant \( ^{1} \text{H} \) coupling constant. The \( D_4 \) structure of \( \text{C}_{70} \) suggests a linear connectivity of the five carbon types, with the polar carbons (labeled a) representing one end of the connectivity and the belt carbons (e) representing the other. The 2D spectrum reveals the four connectivities, showing a single string of connected resonances, with respective intensities 10:20:10:20, solidly supporting the \( D_4 \) structure. The crucial connectivity is obtained between the two intensity 10 lines at 150.8 ppm and 147.8 ppm, forcing the assignment of the line at 150.8 ppm to the polar end cap carbon a, and hence the remaining assignments. We note that the resonances correlating a to b are the least intense, as only one out of the three bonds of an end cap carbon a connects to a carbon b. In contrast, the belt carbons e at 130.8 ppm are each bonded to two type-d carbons at 144.4 ppm, giving cross peaks twice as intense as those revealing the a-b connectivity. The small separation between resonances b and c gives rise to second-order effects in the cross peaks, reducing the outer line of each multiplet.\(^{27} \) These results confirm the assignments of ref 8.

Taylor et al.\(^{8} \) noted that the \( \text{C}_{70} \) chemical shifts indicated torsional strain. Belt carbon e resonating at 130.8 ppm can be contrasted to similar carbons in benzo[cy]pyrene (125.5 and 123.8 ppm);\(^{28} \) the downfield position of e is consistent with torsional strain (e.g., the bridgehead carbons in paracyclophane\(^{29} \) resonate at 140.4 ppm). However, while carbon a has a similar structural environment to those in \( \text{C}_{60} \), it resonates 7 ppm further downfield. The origin of this relative shift is not clear, but may be due to differences in ring currents or aromaticity between the two molecules.\(^{29,30} \)

One-bond carbon—carbon coupling constants (\( J_{CC} \)) in polycyclic aromatic compounds generally range from 53 to 63 Hz.\(^{31} \) It has been concluded that the size of the coupling is related to the s character of the bond, and a linear correlation between \( J_{CC} \) and decreasing bond lengths or increasing r-bond orders has been observed in model compounds and relative strain in the molecule. However, unequivocal experimental assignment of the lines is clearly desirable.
suggested by several groups for polycyclic aromatic compounds. A value of $J_{10}$ of 45 Hz for azulene was interpreted as evidence for this bond being weak. For C$_{60}$, the 2D spectrum gives the $J_{CC}$ values: $J_{ab} = 68$, $J_{bc} = 55$, $J_{cd}$ = 55, and $J_{de} = 62$ Hz. These values indicate that the four bonds have substantial s character and π-bond order. Bonds d–e and a–b fuse six-membered rings and may be compared with $J_{10}$ in 1-methyl- and 2-methynaphthalene at 52 and 53 Hz, respectively. In analogy with cyclopropane derivatives, the larger value of $J_{ab}$ may arise from both carbons in bond a–b belonging to five-membered rings, whose bonds have greater p character due to smaller internal angles. This should increase the s character of the a–b bond and hence the coupling constant; this effect should be less for bond d–e, as this bond has only carbon in a five-membered ring. We note that the large values for $J_{CC}$ we report are evidence against proposed structures for fullerenes involving three-membered rings, as by analogy with cyclopropane derivatives, these rings would be expected to have markedly small coupling constants.

The 2D NMR spectrum of C$_{70}$ yields bonding topology, coupling constants, and a definitive assignment of the 13C NMR. The 2D NMR spectrum gives the $J_{CC}$ values: $J_{ab}$, $J_{bc}$, $J_{cd}$, $J_{de}$, $J_{ef}$, $J_{fg}$, $J_{gh}$, $J_{ab}$, as evidence against proposed structures for fullerenes involving three-membered rings, as by analogy with cyclopropane derivatives these rings would be expected to have markedly small coupling constants.

Expression of yeast metallothionein, which binds copper specifically, is regulated by the protein CUP2 (also known as ACE1). CUP2 itself is activated for binding to DNA by copper(1). Yeast metallothionein contains a cluster of eight copper(1) ions bridged by thiolate ligands that are likely provided by the 12 cysteines of the protein. How copper is bound to CUP2 extended X-ray absorption fine structure (EXAFS) gives strong evidence that the copper ions bound to CUP2 are sulfur-coordinated and in close proximity to each other, most likely bridged by thiolate sulfurs. The Cu K-edge X-ray absorption edge structure demonstrates that the copper and CUP2 are in the +1 oxidation state and furthermore indicates that their electronic environment is closest to s-fold coordination.

Cu K-edge X-ray absorption spectra were collected at the Stanford Synchrotron Radiation Laboratory on wiggler beam line 4-2 (unfocused) under dedicated ring conditions (3.0 GeV, 70-90 mA) using a Si(220) double-crystal monochromator. Protein

Figure 1. EXAFS data for CUP2. The solid line is the raw data. The dashed line is the data obtained by Fourier transforming the data into $k$ space, applying a filter from 0.80 to 3.35 Å, and back-transforming. The dotted line is the calculated EXAFS from two-shell fits described in the text and reported in Table I.

Figure 2. Comparison of the Fourier transform on filtered EXAFS data ($R = 0.80-3.35$ Å, $\lambda$ range of 3.0-10.0 Å$^{-1}$) from CUP2 (solid line) with transforms of a one-shell fit containing S (dashed line) and a two-shell fit containing S and Cu (dotted line). Notice the excellent agreement between the fit and data for the first shell in both cases. However, while the second peak is not reproduced by a single S shell, it is well reproduced with the presence of a second shell of Cu.
