GENERALIZATIONS OF THE RECURSION THEOREM

SEBASTIAAN A. TERWIJN

Abstract. We consider two generalizations of the recursion theorem, namely Visser's ADN theorem and Arslanov's completeness criterion, and we prove a joint generalization of these theorems.

§1. Introduction. The recursion theorem is a classic result in computability theory. It was found by S. C. Kleene in his study of the λ -calculus, and first appeared in [11]. (It appears somewhat hidden, on p. 153, in the last paragraph of Section 2.) In the following, φ_n denotes the n -th partial computable (p.c.) function, in some standard numbering of the p.c. functions.

THEOREM 1.1 (The recursion theorem, Kleene [11]). *Let f be a computable function. Then f has a fixed point, that is, there exists a number e such that $\varphi_{f(e)} = \varphi_e$.*

The recursion theorem allows for certain kinds of circular definitions, which gives the result an air of mystery. The proof of this theorem is very short, but somewhat enigmatic. An illuminating way to view it, namely as a diagonalization argument that fails, was given by Owings [16].

Kleene actually proved the following version of the recursion theorem, that we will use below. For a thorough discussion of this second version see Moschovakis [14].

THEOREM 1.2 (The recursion theorem with parameters, Kleene [11]). *Suppose that $h(n, x)$ is a computable binary function. Then there exists a computable function f such that for all n , $\varphi_{f(n)} = \varphi_{h(n, f(n))}$.*

Note that for every fixed n , the computable function $h(n, x)$ has a fixed point by the recursion theorem. The second version with parameters says that this holds *uniformly*. (One can even have h partial computable, and stipulate that in the case where it is not defined $\varphi_{h(n, x)}$ denotes the totally undefined function.)

We will discuss two generalizations of the recursion theorem. First we discuss the ADN theorem, proved by Visser in 1980, with motivations from λ -calculus, arithmetic provability, and the theory of numerations. We give a proof of the ADN theorem from the recursion theorem with parameters. Second, we discuss Arslanov's completeness criterion from 1977/1981, which generalizes the recursion theorem

from computable functions to A -computable functions, for any set A of incomplete c.e. degree. We then proceed to prove a joint generalization of these two theorems.

Our notation from computability theory is mostly standard. Partial computable (p.c.) functions are denoted by lower case Greek letters, and (total) computable functions by lower case Roman letters. ω denotes the natural numbers, φ_e denotes the e -th p.c. function, and W_e denotes the domain of φ_e . We write $\varphi_e(n) \downarrow$ if this computation is defined, and $\varphi_e(n) \uparrow$ otherwise. We let $\langle e, n \rangle$ denote a computable pairing function. \emptyset' denotes the halting set. For unexplained notions we refer to Odifreddi [15] or Soare [17].

§2. Diagonally noncomputable and fixed point free functions. A function f is called *fixed point free*, or simply FPF, if $W_{f(n)} \neq W_n$ for every n . Note that by the recursion theorem no FPF function is computable. We will also consider *partial* functions without fixed points. Extending the above definition, we call a partial function δ FPF if for every n ,

$$\delta(n) \downarrow \implies W_{\delta(n)} \neq W_n. \quad (1)$$

Below, by FPF function we will always mean a total function, unless explicitly stated otherwise.

A function g is called *diagonally noncomputable*, or DNC, if $g(e) \neq \varphi_e(e)$ for every e .

We are interested in the Turing degrees of sets computing FPF or DNC functions. It is well-known that these coincide:

PROPOSITION 2.1 (Jockusch et al. [7]). *The following are equivalent for any set A :*

- (i) A computes a FPF function,
- (ii) A computes a DNC function,
- (iii) A computes a function f such that $\varphi_{f(e)} \neq \varphi_e$ for every e .

A proof of Proposition 2.1 can be found in Downey and Hirschfeldt [5, p. 87]. Degrees of $\{0, 1\}$ -valued DNC functions are also called PA-degrees, as they coincide with degrees of complete extensions of Peano arithmetic, cf. Jockusch and Soare [8], [5, p. 89].

The article Kjos-Hanssen, Merkle, and Stephan [10] contains a discussion linking various classes of DNC functions to Kolmogorov complexity. Since by Theorem 4.1 below (in combination with Proposition 2.1), the recursion theorem fails for a c.e. Turing degree if and only if it contains a DNC function, this also provides a link between the recursion theorem and Kolmogorov complexity.

§3. The ADN theorem. Motivated by the λ -calculus, arithmetic provability, and the theory of numerations, Visser [19] proved the following generalization of the recursion theorem, called the ADN theorem. ADN theorem stands for “anti diagonal normalization theorem”. Applications of this theorem are discussed in Visser (for the λ -calculus and numerations), Bernardi and Sorbi [4] (m-completeness of ceers), and Barendregt [3] (in which the ADN theorem is used to prove a result of Statman’s). See also the discussion on computably enumerable equivalence relations and arithmetic provability in Bernardi and Sorbi [4] and Montagna and Sorbi [13].

It should be noted that the ADN theorem was originally formulated by Visser in a more general form, namely for arbitrary precomplete numberings, in the sense of Ershov [6]. (Ershov also formulated a more general version of Theorem 1.1 in this context.) We refrain from discussing this more general form here, but simply note that the version below corresponds to the case of a standard numbering of the c.e. sets.

THEOREM 3.1 (ADN theorem, Visser [19]). *Suppose that δ is a partial computable fixed point free function. Then for every partial computable function ψ there exists a computable function f such that for every n ,*

$$\psi(n) \downarrow \implies W_{f(n)} = W_{\psi(n)}, \tag{2}$$

$$\psi(n) \uparrow \implies \delta(f(n)) \uparrow. \tag{3}$$

DEFINITION 3.2. In the following, if (2) holds for every n , we will say that f *totalizes* ψ . If both (2) and (3) hold, we will say that f *totalizes ψ avoiding δ* .

Note that the ADN theorem implies the recursion theorem: The function δ cannot be total, for otherwise $f(n)$ could not exist when $\psi(n) \uparrow$. It follows that there can be no computable FPF function. By Proposition 2.1 this is equivalent to the statement of the recursion theorem.

Visser’s original proof of the ADN theorem mimicked the proof of the recursion theorem. Here we prove the result directly from the recursion theorem with parameters, resulting in the following proof.

PROOF OF THEOREM 3.1. By the recursion theorem with parameters (Theorem 1.2), we can define¹ a computable function f such that

$$\varphi_{f(n)} = \begin{cases} \varphi_{\delta(f(n))} & \text{if } \delta(f(n)) \downarrow \text{ before } \psi(n) \downarrow, \\ \varphi_{\psi(n)} & \text{if } \psi(n) \downarrow \text{ before } \delta(f(n)) \downarrow, \\ \uparrow & \text{otherwise.} \end{cases}$$

Now the first case can never obtain, since δ is FPF. Hence, if $\psi(n) \downarrow$ then $W_{f(n)} = W_{\psi(n)}$, and if $\psi(n) \uparrow$ then $\delta(f(n)) \uparrow$, so f totalizes ψ avoiding δ . \dashv

We note that by taking ψ in Theorem 3.1 universal, we see that the following uniform version holds:

THEOREM 3.3 (ADN theorem, uniform version). *Suppose that δ is a partial computable fixed point free function. Then there exists a computable function f such that for every e the function $f(\langle e, n \rangle)$ totalizes φ_e avoiding δ .*

PROOF. Suppose that $\psi(\langle e, n \rangle) = \varphi_e(n)$ is universal. By Theorem 3.1, there exists a computable f that totalizes ψ avoiding δ . But then, for fixed e , $f(\langle e, n \rangle)$ totalizes φ_e avoiding δ :

$$W_{f(\langle e, n \rangle)} = W_{\psi(\langle e, n \rangle)} = W_{\varphi_e(n)}$$

whenever $\varphi_e(n) \downarrow$, and $\delta(f(\langle e, n \rangle)) \uparrow$ if $\varphi_e(n) \uparrow$. \dashv

¹The formal justification of this runs as follows. By the S-m-n-theorem, define a computable function $h(n, x)$ such that

$$\varphi_{h(n,x)} = \begin{cases} \varphi_{\delta(x)} & \text{if } \delta(x) \downarrow \text{ before } \psi(n) \downarrow, \\ \varphi_{\psi(n)} & \text{if } \psi(n) \downarrow \text{ before } \delta(x) \downarrow, \\ \uparrow & \text{otherwise.} \end{cases}$$

By Theorem 1.2 there is a computable function f such that $\varphi_{f(n)} = \varphi_{h(n,f(n))}$ for every n .

In other words, if we can totalize a universal ψ avoiding δ , we can uniformly do the same for all φ_e .

§4. Arslanov’s completeness criterion. Let \emptyset' denote the halting set. Obviously, \emptyset' can compute a FPF function. By the low basis theorem [9], there exist FPF functions of low degree. However, these cannot have c.e. degree. On the other hand, by Kučera [12], any FPF degree below \emptyset' bounds a noncomputable c.e. degree. The Arslanov completeness criterion says that for c.e. degrees, containing a FPF function characterizes Turing completeness. Namely, if A is a Turing incomplete c.e. set, then A does not compute a FPF function. This shows that the recursion theorem holds for any function f that is computable by some incomplete c.e. set A , rather than just the computable ones. Arslanov proved this elegant characterization by extending work of Martin and Lachlan, cf. Soare [17, p. 88].

THEOREM 4.1 (Arslanov completeness criterion [1], [2]). *Suppose A is c.e. and $A <_T \emptyset'$. If f is an A -computable function, then f has a fixed point, i.e., there exists $e \in \omega$ such that $W_{f(e)} = W_e$.*

This result also holds for other notions of reduction, such as m- and wtt-reducibility (cf. [15, pp. 308, 338]).

Note the following analogous results for the PA-degrees mentioned above: Again, by the low basis theorem, PA-degrees can be low, but by Jockusch and Soare [8], a c.e. PA-degree must be complete.

The Arslanov completeness criterion has been extended in various ways, by considering relaxations of the type of fixed point, e.g., instead of requiring $W_{f(e)} = W_e$, requiring merely that $W_{f(e)}$ is a finite variant of W_e (Arslanov), or that they are Turing equivalent (Arslanov), or that the n -th jumps of these sets are Turing equivalent (Jockusch). In this way the completeness criterion can be extended to all levels of the arithmetical hierarchy. For a discussion of these results we refer the reader to Soare [17, p. 270 ff] and Jockusch, Lerman, Soare, and Solovay [7]. The latter article also contains an extension of Theorem 4.1 from c.e. degrees to d.c.e. degrees.

By the following proposition, for a given FPF function δ , we may assume without loss of generality that δ is defined on the set $\{a \mid W_a \neq \emptyset\}$. In particular, we see that the difficulty of producing a total FPF function lies in the set of c.e. codes for the empty set. This will also play a role in the proof of Theorem 5.1 below.

PROPOSITION 4.2. *Suppose δ is a partial FPF function. Then δ computes a partial FPF function $\hat{\delta}$ such that $\{a \mid W_a \neq \emptyset\} \subseteq \text{dom}(\hat{\delta})$.*

PROOF. Fix a code d such that $W_d = \emptyset$, and define

$$\hat{\delta}(a) = \begin{cases} \delta(a) & \text{if } \delta(a) \downarrow \text{ before } W_a \neq \emptyset, \\ d & \text{if } W_a \neq \emptyset \text{ before } \delta(a) \downarrow, \\ \uparrow & \text{otherwise.} \end{cases}$$

Clearly, $\hat{\delta}$ is FPF, and defined on $\{a \mid W_a \neq \emptyset\}$. ◻

§5. A joint generalization. In this section we prove a joint generalization of the ADN theorem and Arslanov’s completeness criterion. The latter generalizes the recursion theorem from computable functions to arbitrary functions bounded by

an incomplete c.e. Turing degree. The ADN theorem is a statement about partial computable FPF functions δ . We show that this can also be generalized to partial A -computable FPF functions δ , with A c.e. and Turing incomplete. This results in a statement simultaneously generalizing Arslanov's completeness criterion and the ADN theorem.

THEOREM 5.1 (Joint generalization). *Suppose that A is a c.e. set such that $A <_T \emptyset'$, and suppose that δ is a partial A -computable fixed point free function. Then for every partial computable function ψ there exists a computable function f totalizing ψ avoiding δ , i.e., such that for every n ,*

$$\psi(n) \downarrow \implies W_{f(n)} = W_{\psi(n)}, \tag{4}$$

$$\psi(n) \uparrow \implies \delta(f(n)) \uparrow. \tag{5}$$

PROOF. Suppose A is a c.e. set, and suppose that δ is a partial A -computable FPF function for which the statement of the theorem does not hold, i.e., there exists a ψ such that all f fail to totalize ψ avoiding δ . Without loss of generality, ψ is universal by the same reasoning as in Theorem 3.3. We prove that $\emptyset' \leq_T A$.

Given x , we define a computable function f in such a way that the code of f depends uniformly on x . Later we will decide with A whether $x \in \emptyset'$ depending on what happens with f .

We say that f totalizes ψ at stage s if for all $n \leq s$

$$\psi_s(n) \downarrow \implies W_{f(n),s} = W_{\psi(n),s},$$

$$\psi_s(n) \uparrow \implies W_{f(n),s} = \emptyset.$$

Suppose that $\delta = \{e\}^A$, and consider the approximation

$$\delta_s(x) = \{e\}_s^{A_s}(x).$$

Note that if $\delta_s(x) \downarrow$ the computation does not have to be permanent; it can change later if A changes below the use, i.e., if $A_s \upharpoonright u \neq A \upharpoonright u$ for the use u of this computation. Also, it is possible that $\delta_s(x) \downarrow$ infinitely often, but $\delta(x) \uparrow$. Now if $\delta_s(x) \downarrow$, and $A_s \upharpoonright u = A \upharpoonright u$, then we know that the computation is permanent, i.e., $\delta_s(x) = \delta(x)$. Because A is c.e., we can see with A whether a computation $\delta(x)$ is permanent by checking that A is permanent below the use. So if we know that $\delta(x) \downarrow$ for certain x , there have to be stages s where this computation is permanent, and hence we can find such x computably in A .

Below, we will also search without A for x and s such that $\delta_s(x) \downarrow$ appears to be permanent. A complication here is that if x is the least such number, there may be $y < x$ such that $\delta_t(y) \downarrow$ at every stage t , but $\delta(y) \uparrow$, so our search never reaches x .² To prevent this, we use a special order of search L in which every number occurs infinitely often.

Construction of f . Given x , we define f as follows. To make f total, at stage $s = 0$ we define $W_{f(n),0} = \emptyset$ for all n .

²Even if we use the convention, customary in infinite injury arguments, that $\delta_t(y) \uparrow$ for at least one stage t after the computation changes, there might be several $y < x$ taking turns in preventing us to reach x .

Fix a computable order L of natural numbers in which every number occurs infinitely often, for example

$$1, 1, 2, 1, 2, 3, 1, 2, 3, 4, \dots, 1, 2, 3, \dots n, \dots$$

At stage s , we search for the L -least n with $n \leq s$ (in the usual order) such that

$$\psi_s(n) \uparrow \text{ and } \delta_s(f(n)) \downarrow, \tag{6}$$

and such that this copy of n in L was not previously discarded. If no such n is found, we let f totalize ψ at stage s .

If n is found, we freeze f , meaning that for subsequent stages t , as long as f is frozen we have $W_{f(n),s} = W_{f(n),t}$ for every n .

We freeze f until (if ever) we find a stage $t > s$ such that one of the following happens:

- At stage t we see that $\delta_s(f(n))$ was not permanent, either because $\delta_t(f(n)) \uparrow$ or because A has changed below the use of the computation. Then we unfreeze f by letting f totalize ψ at stage t , we discard this copy of n in L , and search for a new stage s and n as in (6).
- $x \in \emptyset'_t$. Since $W_{f(n),s} = \emptyset$ (because $\psi_s(n) \uparrow$), we can let $f(n)$ follow $\delta_s(f(n))$, meaning that $W_{f(n)} = W_{\delta_s(f(n))}$. (Note that this makes the definition of $f(n)$ circular, so formally we are applying the recursion theorem with parameters (Theorem 1.2) here.)

This concludes the construction of f . We make the following observations.

To fail the statement of the theorem, δ has to kill all functions f totalizing ψ , (i.e., such that (4) holds), by making (5) fail. This means that δ has to engage some $f(n)$ with $\psi(n) \uparrow$ by becoming defined on it. Now as long as this has not happened, f is totalizing ψ , so sooner or later $\delta(f(n)) \downarrow$ has to happen for some n , meaning that $\delta_s(f(n)) \downarrow$ is permanent from some stage s onwards. Note that there may be fake computations $\delta_s(f(n)) \downarrow$, but every time such a computation is found to be fake, f proceeds to totalize ψ for at least one stage, thus keeping the pressure on δ .

Now if $x \notin \emptyset'$, then f settles on such a permanent computation $\delta_s(f(n))$, meaning that at some stage s , n as in (6) is found, f is frozen, and never changes after that. This is because of our special search procedure using the order L : If there are fake computations $\delta_t(y) \downarrow$ with $y < f(n)$, then these are all discarded after finitely many stages. It may be that $y < f(n)$ and $\delta_t(y) \downarrow$ for infinitely many t , but every time f freezes on such a computation, and this computation changes later, a copy of y in L is discarded, and only finitely many copies of y occur before $f(n)$ in L .

The decision procedure for $\emptyset' \leq_T A$. Given x , we decide whether $x \in \emptyset'$ using A . Note that the definition of f above uniformly depends on x (meaning that there is a computable function h such that $f = \varphi_{h(x)}$ for every x). Following the definition of f , we search for a point $f(n)$ where δ engages f by becoming defined. As pointed out above, such a point exists, since otherwise f would totalize ψ , and also (5) would hold. Hence we find a stage s and n such that $\delta_s(n) \downarrow$ and f is frozen at stage s . If the computation $\delta_s(n) \downarrow$ is not permanent (which we can see by checking $A_s \upharpoonright u \neq A \upharpoonright u$, with u the use of the computation),

then we search on. Continuing in this way, we either find a stage s with $x \in \emptyset'_s$, or a pair n and s such that the computation $\delta_s(f(n)) = \delta(f(n)) \downarrow$ is permanent.

In the first case we know of course that $x \in \emptyset'$, and we are done. Note that it could happen that x enters \emptyset' at a stage t where f is frozen on a nonpermanent computation $\delta_s(f(n))$, and hence $f(n)$ starts to follow this nonpermanent computation $\delta_s(f(n))$. In that case there does not need to be any final permanent computation $\delta(f(n))$. But this is immaterial for our case distinction: We either find that $x \in \emptyset'$ or we find a permanent computation $\delta_s(f(n))$.

In the second case we know that f is eventually frozen on the permanent computation $\delta_s(f(n))$, and that it will never change to another n . In this case we also know that $x \notin \emptyset'$, for otherwise $f(n)$ would start to follow $\delta_s(f(n))$, and hence $\delta_s(f(n))$ would have to change. Thus we can decide $x \in \emptyset'$ for every x . \dashv

Note that for computable A , the statement of Theorem 5.1 is the same as Visser's ADN theorem. Also, the theorem implies Arslanov's completeness criterion, since in general f as in the theorem cannot satisfy (5) if δ is total. In particular, any total A -computable δ cannot be FPF, hence must have a fixed point.

One can still ask precisely for which class of oracles A the statement of Theorem 5.1 holds. By the theorem itself, it includes all c.e. A of incomplete Turing degree. By the argument just made, it also excludes all A of FPF degree. At this point we do not know whether this class is equal to all A that are not of FPF degree.

As we have seen, the recursion theorem is effective, in the sense that the fixed point from the statement of the theorem can be found effectively. This is the content of the recursion theorem with parameters (Theorem 1.2). One may wonder if the same holds for the ADN theorem (when appropriately formulated), Arslanov's completeness criterion, or their joint generalization Theorem 5.1. Note that the ADN theorem can be proved using the recursion theorem with parameters (see the proof given in Section 3 above). It stands to reason that its generalized version might be provable from a parameterized version of Arslanov's completeness criterion. However, this does not work: As it turns out, neither the ADN theorem nor Arslanov's completeness criterion has a version with parameters. This is proven in [18]. As there are no parameterized versions of these theorems, a fortiori, neither is there such a version for their joint generalization.

Finally, we note that the ADN theorem is effective in the following sense. We have already seen that it is uniform in a code of ψ (as observed in Theorem 3.3). Also, from the proof of the ADN theorem in Section 3, it is clear that the code of the function f depends effectively on a code of δ . Hence the result is uniform in both ψ and δ . A similar uniformity does not hold for the joint generalization Theorem 5.1: It is still uniform in ψ , but not in codes for A and δ , as is proven in [18]. Hence the proof of Theorem 5.1 given above is necessarily nonuniform.

Acknowledgments. We thank Henk Barendregt for drawing our attention to the ADN theorem and for discussions in general, and an anonymous referee for several suggestions.
